ABSTRACT

Objectives: In 2014, a population-screening program using immuno-faecal occult blood testing (I-FOBT) has started in the Netherlands. The aims of this study were to evaluate the proportion of individuals in the Dutch screening program with a positive I-FOBT that fulfill the criteria for familial colorectal cancer (FCC) and to evaluate the proportion of participants that needs genetic counseling or colonoscopic surveillance.

Material and methods: This retrospective observational study was performed in two large hospitals. Individuals aged between 55 and 75 years with a positive I-FOBT that underwent colonoscopy were included. A detailed family history was obtained in all individuals.

Results: A total of 657 individuals with a positive I-FOBT test underwent colonoscopy. A total of 120 (18.3%) participants were found to have a positive family history for CRC, 20 (3.0%) fulfilled the FCC criteria, 4 (0.6%) the Bethesda guidelines and 1 (0.2%) participant the Amsterdam criteria. Multiple adenomas (>10) were found in 21 (3.2%) participants. No cases of serrated polyposis were identified. Based on these criteria and guidelines, a total of 35 (5.3%) required referral to the clinical geneticist and the relatives of 20 (3.0%) participants should be referred for surveillance colonoscopy.

Conclusion: Obtaining a detailed family history at the time of intake of participants with a positive I-FOBT in the Dutch surveillance program increased the identification of participants with familial CRC.

Introduction

Colorectal cancer (CRC) is one of the most common cancers in the Western world. More than 13,000 patients are annually diagnosed with CRC in the Netherlands and over 5000 patients die due to this condition.[1] When CRC is detected because of symptoms, about 45% of the patients have a metastatic disease. Worldwide screening programs have been implemented in order to prevent the development of CRC and to diagnose CRC at an early stage that allows curative treatment.[2–4]

In February 2014, a national screening program has started in the Netherlands.[5] Individuals aged between 55 and 75 years are offered colorectal testing using a biennial immuno-faecal occult blood test (I-FOBT) and participants with a positive I-FOBT are referred for colonoscopy.[5–7] Previous studies have suggested that this program will lead to a reduction of CRC by 20–25%.[2,8]

In approximately 10–15% of the CRC cases, CRC is caused by a combination of hereditary and environmental factors.

In 3 to 5% of all cases CRC is due to a hereditary CRC syndrome including Lynch syndrome or one of the polyposis syndromes.[9,10] The term “familial CRC” (FCC) is used for individuals with a clinically relevant increased risk (relative risk >3) of CRC which justifies surveillance by colonoscopy.[11–13] These individuals have one first degree relative (FDR) with early onset (<50 years) CRC or two FDR with CRC diagnosed at any age. The lifetime risk of developing CRC for these individuals varies from 10 to 25%, depending on the number of relatives with CRC and the age at diagnosis.[14]

In the Netherlands, it has been estimated that about 100,000 subjects have familial CRC,[9] but unfortunately, most of these people are still unrecognized. An important way to improve the identification of familial and hereditary CRC during the population screening for CRC is by informing them about the risk factors including hereditary factors for CRC at invitation (by a brochure which is attached to the invitation letter including a referral to the website <http://www>.

bevolkingsonderzoekdarmkanker.nl) [15] and by obtaining an appropriate family history in individuals with a positive test result that are referred for colonoscopy.[16]

The aims of this study were to evaluate the proportion of individuals with a positive I-FOBT that comply with the criteria of familial/hereditary CRC in the Dutch population-screening program, and to evaluate the proportion of patients that need further genetic analysis based on their personal and family history and/or endoscopic findings.

Methods

Study population and study design

This retrospective observational study was performed at the department of gastroenterology and hepatology of the Leiden University Medical Center (LUMC) in Leiden and the Isala Clinics in Zwolle, the Netherlands. All participants aged between 55 and 75 years with a positive I-FOBT and who underwent a colonoscopy between February and October 2014 in Leiden and between March 2014 and November 2015 in Zwolle were included. In both centers a detailed family history was obtained before colonoscopy. Participants included in the LUMC were requested to complete a questionnaire about their family history (Figure 1). Based on this questionnaire, the participants had a significant positive family history if the family history fulfills the criteria of familial CRC,[17] Amsterdam criteria [13,18,19] or the Bethesda guidelines [20,21] (Table 1). These criteria and guidelines were used to identify individuals that should be referred to the clinical geneticist or should be advised colonoscopic surveillance.[22]

Colonoscopies were performed by experienced endoscopists certified by the population-screening program and polyps detected at colonoscopy were removed if possible. The removed polyps were evaluated by pathologists also certified by the population-screening program. The study was approved by the institutional medical ethical committee of the LUMC.

Data collection

All informations concerning the family history obtained during intake and colonoscopy results from the participants were collected in a database. The following information was extracted from the database and questionnaires: demographical data, personal history (CRC, Lynch syndrome-associated tumors (LS-AT; tumors of the colon, endometrium, stomach, small intestine, urethra, bile ducts, pyelum, pancreas, ovary or brains) or other tumors) and family history for CRC (number of FDRs and/or second degree relatives (SDRs) with CRC and age at diagnosis).

Statistical methods

Descriptive statistics were used to characterize the study population, family history and familial CRC risk. Primary outcome measures were positive family history for CRC and fulfillment of the criteria for familial CRC, Bethesda guidelines

and Amsterdam Criteria. All statistical analyses were performed using SPSS 22.0 (Chicago, IL).

Results

Colonoscopic findings

A total of 657 participants with a positive I-FOBT underwent colonoscopy and familial cancer risk assessment. The mean age of the study population was in 70.8 years in Leiden and 67.8 years in Zwolle and participants were predominantly male (57.8 and 62.7%). The findings at colonoscopy of both centers are described in Table 2. A total of 49 participants (7.5%) were diagnosed with CRC and 280 (42.6%) had advanced adenomas (AAP). Multiple adenomas (2 or more) were found in 368 (56.0%) participants and more than 10 adenomas were observed in 21 of the 657 cases (3.2%). In 151 participants serrated polyps were found, none of them complied with the criteria for serrated polyposis.

Personal and family history of CRC

In total, 120 of the 657 participants (18.3%) had at least one FDR with CRC. Twenty individuals (3.0%) complied the criteria for familial CRC and 4 (0.6%) fulfilled the Bethesda guidelines. One individual (0.2%) met the Amsterdam criteria. The results of family and personal history are shown in Table 3. No significant correlation was found between a positive family history and having multiple adenomas (>10) or advanced adenomas.

A total of 35 (5.3%) participants should be referred to the clinical geneticist (Table 4) and the relatives of 20 (3.0%) participants should be referred for surveillance colonoscopy (Table 3) according to the clinical guidelines mentioned before.

Discussion

This study demonstrated that a detailed family history and/or the use of a family history questionnaire at the time of intake of participants with a positive I-FOBT in the Dutch surveillance program led to the identification of familial CRC families in approximately 3% of the cases. Moreover, a substantial proportion of participants were found to have multiple adenomas (>10) and need further genetic testing for MUTYH and APC-mutations.

Two previous pilot studies have been performed to identify familial CRC in individuals that participate in a I-FOBT population screening. The first study performed by Dekker et al. in 2011 in the Netherlands showed that 17% of the participants with a positive I-FOBT in the CRC screening program had a positive family history of CRC. Six percent of the participants had an increased familial CRC risk and approximately 4% had an increased familial CRC risk according to the Bethesda guidelines and/or Amsterdam Criteria. No significant differences were found with respect to colonoscopy results between the participants with an average versus an increased familial CRC risk.[23] The second study, conducted in 2006 in

Figure 1. Questionnaire to assess the familial CRC risk given at intake.

Australia, reported a positive family history for CRC in 19.6% of subjects that participated in a I-FOBT screening program. Fourteen percent had an increased familial CRC risk. Of these participants, 4.2% had a high familial risk sufficient to warrant colonoscopic surveillance.[24] Although both studies showed that a substantial proportion of individuals with a positive I-FOBT result had a positive family history for CRC, detailed information on the family history and the level of CRC risk was lacking. Also, the identification of polyposis syndromes was not addressed.

In this study, 120 (18.3%) participants were found to have a positive family history for CRC in FDR and 4 (0.6%) had a positive family history for a LS-AT. It was found that 3.0% of the participants fulfilled the criteria for familial CRC and 0.6% the Bethesda guidelines. One participant fulfilled the Amsterdam criteria. Multiple adenomas (>10) were found in 21 participants (3.2%) and no cases of serrated polyposis were detected. Based on the findings according to the current clinical guidelines, a total of 35 (5.3%) participants should be referred to the clinical geneticist and relatives of

20 (3.0%) participants should be referred for surveillance colonoscopy.

Several studies have indicated that the identification of individuals with familial cancer and Lynch syndrome is sub-optimal.[25] A previous Dutch study estimated that 100,000 individuals are at risk for familial or hereditary CRC but currently only a small proportion of these individuals have been recognized.[9] A nationwide population-screening program such as the I-FOBT program in the Netherlands may not only improve the prognosis of patients with CRC and prevent the development of CRC but also may identify high risk individuals. The program provides full information (website and pamphlets) about the fact that a proportion of patients with CRC is caused by genetic factors. In addition, obtaining a detailed family history in all cases with a positive I-FOBT will identify many cases with an increased risk of CRC which is demonstrated in this study. Systematic use of a family history questionnaire may further improve the identification.

The presence of multiple adenomas may also indicate an underlying genetic disorder i.e., polyposis. There is no agreement about the number of adenomas that justifies referral to a clinical geneticist for analysis of mutations in the MUTYH-gene and the APC-gene. Originally, the presence of 10 or more adenomas was a criterion for referral. However, a recent study showed that mutations were rarely detected in patients with 10–20 adenomas (mutation detection rate ~3%) and the mutation detection rate increased in patients with >20 adenomas.[26]

The prevalence of serrated polyposis is still unknown. In this study, no cases were identified. It is well known that serrated polyps are difficult to detect.[10] However, in this study experienced gastroenterologists are certainly able to identify this syndrome.

Regarding the identification of Lynch syndrome, currently, in many countries universal screening is being implemented. This means that all patients with CRC under the age 70 years (or in some countries all CRC patients independent of the age) are tested for expression of the mismatch repair proteins

Table 3. Patients with evidence for familial or hereditary CRC syndromes.

(MMR-proteins) using immuno-histochemical analysis.[22] This new approach will be helpful to identify all Lynch syndrome cases.

The identification of familial CRC will strongly be improved by case finding during population-screening programs. The age distribution of CRC in familial CRC (50–75 years) is almost similar as the patients that are invited for the Dutch population-screening program (55–75 years). A recent surveillance study among 550 patients with familial CRC showed that the prevalence of advanced adenomas was two-fold higher than reported in “average risk” individuals.[14] A previous study showed that colonoscopic surveillance led to a reduction of CRC by 80%.[16] Usually, colonoscopic surveillance is recommended in familial CRC with five or six year intervals.[27] However, it is still unknown whether a 10 years interval or two yearly I-FOBT screening is as effective as a five year-interval-colonoscopy surveillance.

Strengths of the study include the cross-sectional design and the full attention that was paid to the family history and the additional use of questionnaires in Leiden to assess the familial CRC risk. In almost all cases, personal and family history was fully verified during intake. Another strength of the study is that the colonoscopies were all performed in two hospitals by well-trained gastroenterologists.

In summary, this pilot study provides a detailed overview of the familial CRC risk assessment in the Dutch I-FOBT screening program that started in 2014. The study demonstrates that a proportion of the patients need further genetic testing and surveillance colonoscopies. The preliminary results of the I-FOBT screening are encouraging. Making optimal use of the patient contact arising from the screening program to identify high risk groups will further improve the prognosis of patients with familial CRC and their families.
