# **Estimation of CO2‑Brine Interfacial Tension Based on an Advanced Intelligent Algorithm Model: Application for Carbon Saline Aquifer Sequestration**

[Meiheriayi](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Meiheriayi+Mutailipu"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) Mutailipu,[\\*](#page-10-0) [Yande](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Yande+Yang"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) Yang, [Kaishuai](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Kaishuai+Zuo"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) Zuo, [Qingnan](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Qingnan+Xue"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) Xue, Qi [Wang,](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Qi+Wang"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) [Fusheng](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Fusheng+Xue"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf) Xue, and Gang [Wang](https://pubs.acs.org/action/doSearch?field1=Contrib&text1="Gang+Wang"&field2=AllField&text2=&publication=&accessType=allContent&Earliest=&ref=pdf)

ABSTRACT: The emission reduction of the main greenhouse gas,  $CO<sub>2</sub>$ , can be achieved via carbon capture, utilization, and storage (CCUS) technology. Geological carbon storage (GCS) projects, especially  $CO<sub>2</sub>$  storage in deep saline aquifers, are the most promising methods for meeting the net zero emission goal. The safety and efficiency of  $CO<sub>2</sub>$  saline aquifer storage are primarily controlled by structural and capillary trapping, which are significantly influenced by the interactions between fluid and solid phases in terms of the interfacial tension (IFT) between the injected  $CO<sub>2</sub>$  and brine at the reservoir site. In this study, a model based on the random forest (RF) model and the Bayesian optimization (BO) algorithm was developed to estimate the IFT between the pure and impure gas−brine binary

systems for application to CO<sub>2</sub> saline aquifer sequestration. Then three heuristic algorithms were applied to validate the accuracy and efficiency of the established model. The results of this study indicate that among the four mixed models, the Bayesian optimized random forest model fits the experimental data with the smallest root-mean-square error (RMSE = 1.7705) and mean absolute percentage error (MAPE = 2.0687%) and a high coefficient of determination ( $R^2$  = 0.9729). Then the IFT values predicted via this model were used as an input parameter to estimate the  $CO<sub>2</sub>$  sequestration capacity of saline aquifers at different depths in the Tarim Basin of Xinjiang, China. The burial depth had a limited influence on the  $CO<sub>2</sub>$  storage capacity.

# **1. INTRODUCTION**

In recent years, reducing anthropogenic carbon emissions has aroused broad concern in countries around the world. Significant amounts of greenhouse gases have been emitted over the years, according to previous research data. $1/2$  $1/2$  $1/2$ Significantly, China, whose energy system mainly relies on fossil fuels, emitted 10.76 GT of  $CO<sub>2</sub>$  and is currently the world's largest emitter of  $CO<sub>2</sub>$ .<sup>[3,4](#page-11-0)</sup> Thus, to address the global warming caused by anthropogenic carbon emissions, China proposed the carbon peak and carbon neutrality goal of the "3060" plan in 2020.<sup>5</sup>

There are several emission reduction methods, including energy structure transformation and energy use efficiency enhancement. Among these methods, the carbon capture, utilization, and storage (CCUS) technique is not only a key technology for reducing carbon emissions but also has significant commercial value compared with other technolo-gies.<sup>[8](#page-11-0)−[10](#page-11-0)</sup> Geological CO<sub>2</sub> storage combined with enhanced water recovery  $(CO_2$ -EWR) technology, considered a newly developed carbon utilization technique, has the ability to safely store a significant amount of  $CO<sub>2</sub>$  without increasing the reservoir pressure, which can be utilized to facilitate reverse

osmosis desalination of reservoir brine to produce drinkable water. $^{11,12}$  $^{11,12}$  $^{11,12}$  This solves the problem of an industry that suffers from water leakage, sometimes discharging wastewater to the neighborhood. Thus, this technology offers a dual solution to environmental and water scarcity challenges. $8,13$  $8,13$  $8,13$  The geological storage and utilization of  $CO<sub>2</sub>$  has great potential both worldwide $11,14,15$  $11,14,15$  $11,14,15$  $11,14,15$  $11,14,15$  and in China, and the Xinjiang region is suitable for  $CO<sub>2</sub>$  saline aquifer sequestration.<sup>[11](#page-11-0)</sup> During this process, the thermodynamic properties of the gas−liquid phase, especially the interfacial tension (IFT) between the gas and liquid phases, play a crucial role in the flexibility of this scheme due to its direct influence on the efficiency of capillary trapping, which is one of the most critical trapping mechanisms in the  $CO_2$  geological storage (CGS) process.<sup>[16](#page-11-0)−[19](#page-11-0)</sup>

Received: May 24, 2024 Revised: August 3, 2024 Accepted: August 7, 2024 Published: August 19, 2024

<span id="page-1-0"></span>In the process of  $CO<sub>2</sub>$  geological storage,  $CO<sub>2</sub>$  is generally in a supercritical state. Supercritical  $CO<sub>2</sub>$  is lifted by buoyancy and settles beneath the cap. The increase in capillary pressure is caused by the numerous linked pore throats of varying sizes in the cap layer, as depicted in Figure 1. The breakthrough

Figure 1. Comparative subsurface  $CO<sub>2</sub>$  flow.

pressure occurs when the pressure differential across the entire cap layer-that is, the pressure differential between the injected  $CO<sub>2</sub>$  and saline water—exceeds the capillary pressure of the pore throat. The nonwetting phase—in this case,  $CO<sub>2</sub>$  flows through the pore throat after the breakthrough pressure is reached, creating issues with  $CO<sub>2</sub>$  leakage. The consequences of capillary pressure breakthrough leakage are severe and occur far more quickly than leakage due to  $CO<sub>2</sub>$  diffusion. Consequently, one of the most critical metrics for evaluating the effectiveness of cap layer sealing is exceeding this threshold capillary pressure. The threshold capillary pressure can be represented by Laplace's law as follows:

$$
Pce \approx \frac{2\sigma \cos \varphi}{R} \tag{1}
$$

where  $P_{ce}$  is the threshold capillary pressure at the orifice throat;  $\sigma$  is the IFT between  $CO_2$  and brine;  $\varphi$  is the contact angle between the caprock,  $CO<sub>2</sub>$ , and brine system; and *R* is the size of the most prominent pore throat or microfracture in the caprock because the larger *R* is, the lower the breakthrough pressure. The orifice throats frequently connect to each other, leading to leakage when the maximum orifice throat is exceeded. It is essential to conduct necessary studies on the influence of temperature, pressure, and other factors on the IFT between the  $CO<sub>2</sub>$  and brine. These findings provide crucial guidance for improving the safety of  $CO<sub>2</sub>$  injection and increasing the capacity for storage.<sup>20</sup> In addition, these studies provide insights into the factors that affect the IFT, which will facilitate future research and advancements in the field.

Numerous academic researchers have conducted extensive investigations on the IFT in  $CO<sub>2</sub>$ -brine systems utilizing a wide range of approaches, including experimental measure-ments,<sup>[21](#page-11-0)−[27](#page-11-0)</sup> molecular dynamics simulations,<sup>28,[29](#page-11-0)</sup> empirical formulations,  $30,31$  density gradient models,  $32$  machine learn-ing,<sup>33–[35](#page-11-0)</sup> and various other techniques. Li et al.<sup>36</sup> conducted IFT measurements on a mixed salt system (0.864 NaCl and 0.136 KCl) using the pendant drop method and discovered a linear relationship between the IFT and the salt concentration. They also developed empirical equations with high accuracy and reached a good agreement with the experimental data. In our previous work, we $37$  analyzed the relationships between the

IFT and temperature, pressure, and salinity in detail via the pendant drop method. The results indicate that in the lowpressure phase, the IFT between  $CO<sub>2</sub>$  and brine decreases markedly with the increase in pressure. Upon reaching the high-pressure regime, the IFT enters a pseudoplateau where it becomes pressure-independent. In contrast, they fluctuate with temperature and increase with molality. Jerauld et al. $38$ improved the empirical formula for the IFT in a  $CO_2$ -brine system. This empirical formula improved the correlation between the IFT and temperature, reducing the standard deviation to 3.4%. Iglauer et al. $^{29}$  $^{29}$  $^{29}$  utilized molecular dynamics to simulate IFT phenomena and discovered that their model aligned with the experimental data. However, it was not a reliable predictor at high pressures, exhibiting an error rate of up to 20%. As a result, the inclusion of a correction factor became necessary.

With the rapid development of computer science, machine learning has also experienced significant growth and is now being applied in various fields. Many scholars have recognized its effectiveness in multiple areas.<sup>[39](#page-12-0)</sup> Ratnakar et al.<sup>[40](#page-12-0)</sup> used machine learning to develop models for predicting the solubility of carbon dioxide in brine. They utilized two primary models, namely, a random forest and a decision tree. The final predictions of the models exhibited a relative error of 2−7% compared to the experimental observations. Liu et al. $41$ constructed an optimized wavelet neural network to predict the IFT of a CO<sub>2</sub>−brine system with a Model R<sup>2</sup> of 0.95 but used a small data set. Amooie et al. $42$  conducted a machine learning prediction of IFT for a  $CO<sub>2</sub>$ −brine system. However, the model they used was outdated. Amar<sup>33</sup> studied an IFT system, using genetic programming to improve the system.

Currently, machine learning has been widely used in various fields due to its high computing speed, strong adaptability, and fault tolerance.<sup>[43](#page-12-0)</sup> A random forest model combined with the Bayesian optimization algorithm (BO-RF) was developed to estimate the IFTs between  $CO<sub>2</sub>$  and brine/water binary systems corresponding to the CGS conditions in this work. In regard to predictors, random forests outperform other conventional models and exhibit better stability. However, a disadvantage of random forests is that they erode over time, in contrast to the recently proposed hybrid algorithms. Here, a Bayesian optimization algorithm was applied to optimize the random forest hyperparameters to increase the accuracy of the prediction results. Then, the Tarim Basin in China's Xinjiang Province was used as a case study to investigate the influence of the IFT on the estimation of the storage capacity of the selected site. This study provides a high-precision model for interfacial tension acquisition in  $CO<sub>2</sub>$ −brine systems, which may be helpful for  $CO<sub>2</sub>$  geological storage technology.

## **2. METHODOLOGY**

**2.1. Principles of Random Forests.** Breiman<sup>[44](#page-12-0)</sup> proposed random forest (RF), an integrated learning method based on several decision trees (weak learners). Machine learning applies the notion of integrated learning, which is often referred to as ensemble learning. It is an optimized combination of several different models.<sup>[45](#page-12-0)</sup> Weak learners are the models that are employed in this combination, which enables more accurate predictions. The training sample set during training must be used to train these weak learners in a sequential manner. Then, these weak learner models are combined and used for predictions.

*2.1.1. Regression Tree.* In the prediction process of the regression tree model, objective evaluations and decisions are made along the branches of the tree based on the input eigenvalues until the leaf nodes are reached and the prediction is made. The associations are represented using a structure that resembles a tree, in which each inner node represents a feature, each branch represents a value obtained from that characteristic, and each terminal node represents the output of a prediction. The following steps are primarily involved in the creation of regression trees:

1. Selection of features: To obtain the best classification result for the split data set, the selection of the appropriate characteristics for the root node is carried out.

2. A finite number of subsets are created from the training data set, and the division of those subsets can be explained as follows: The *j*th eigenvector value is chosen for the input and output variables. For the purpose of categorizing characteristics and labeling points, the following two subsets are defined:

$$
R_1(j, s) = \{x | x^{(j)} \le s\}
$$
 (2)

$$
R_2(j, s) = \{x | x^{(j)} > s\}
$$
\n(3)

where  $R_1(j, s)$  represents the left subset of the partition of the values *s* of the *j*th feature vector and  $R_2(j, s)$  represents the right subset of the partition of the values *s* of the *j*th feature vector.

The best cutoff variable and cutoff point for resolution are selected as follows:

$$
\min_{j,s} \left[ \min \sum_{x_i \in R_1(j,s)} (y_i - y_1)^2 + \min \sum_{x_i \in R_2(j,s)} (y_i - y_2)^2 \right]
$$
\n(4)

$$
y_m = \frac{1}{N_m} \sum_{x_i \in R_m(j,s)} y_i, \ x \in R_m, \ m = 1, \ 2
$$
 (5)

Iterate over the variable *j*, search the intersection *s* for a fixed intersection variable *j*, choose the (*j*, *s*) that minimizes the above equation, and then divide the set into two subsets in turn. This process is repeated until the end conditions are met.

Regression trees operate on a simple, straightforward basis, which makes them easy to apply. However, they are sensitive to changes in the input data and prone to overfitting. Therefore, a regression tree can be optimized by applying integrated learning or pruning techniques to address the unpredictability problems of the data.

*2.1.2. Random Forest.* Regression trees are the fundamental basis of the random forest method, which integrates several regression trees to improve the accuracy and integrity of predictions, as illustrated in Figure 2. The construction of a random forest is as follows:

1. A data point *n* from the complete training data is chosen, where *n* is much smaller than *N* (the total training data set). This is achieved by selecting the input training data. The outof-bag data are a subset of the complete training data set that cannot be chosen for analysis. Error estimates can be made using this particular subset.

2. At each segment node, *m* features are chosen from the whole feature set *M* to form a regression tree.

3. When building each regression tree, the splitting nodes are selected according to the lowest Gini index. Until the maximum depth of the tree is reached or all training samples

Figure 2. Random Forest flowchart.

within a node belong to the same class, the remaining nodes of the regression tree are built using the same splitting strategy.

4. Steps two and three are repeated multiple times. Each input corresponds to a regression tree. Then, a random forest model that can be used for predictive analysis will be established.

5. When the data to be predicted are entered, multiple regression trees can be used to make decisions at the same time, and the corresponding predicted values are obtained. The regression predicted value should be averaged from the predicted value of each regression tree to meet the final result.

The prediction process of the Random Forest is shown in eq 6 as follows:

$$
h(x) = \frac{1}{n} \sum_{i=1}^{n} h_i(x)
$$
\n(6)

Where *n* represents the number of decision trees, each  $T_i$ providing a prediction  $h_i(x)$  for a given input  $x$ , and the final prediction of the Random Forest, denoted as  $h(x)$ , is the mean of all the predictions from the decision trees.

Following the above steps, a random forest can utilize the combination of results from multiple regression trees to make regression predictions. This approach can reduce the variance of the model and enhance its generalization ability.

**2.2. Principles of Bayesian Optimization Algorithms.** To guarantee quick and accurate predictions while using a random forest for regression forecasting, it is critical to determine the model's optimal hyperparameters. In this study, the Bayesian optimization algorithm was used as a global optimization technique to determine the ideal hyperparameters for this model. Bayes theorem is the primary tool used in this method to identify the best results. To precisely fit the genuine goal function and determine the next evaluation position based on the fitted function, a probabilistic agent model was applied. This improves the search efficiency and makes it possible to find the ideal fit more quickly. The Bayesian optimization flowchart is shown in [Figure](#page-3-0) 3. The two main parts of this

<span id="page-3-0"></span>optimization approach are the collection function and the probabilistic agent model.

Figure 3. Flowchart of the Bayesian optimization algorithm.

Models of probabilistic agents can be roughly categorized as parametric or nonparametric. In this study, the collection function was subjected to the confidence boundary technique using a Gaussian process as the nonparametric model.

*2.2.1. Probabilistic Agent Model.* Regression, classification, and other fields require the inference of black-box functions based on Gaussian processes. Additionally, they have less tendency to "overfit". This model was used for this study. Generally, a neural network and a Gaussian process are related. In particular, a neural network with an infinite number of hidden layer units corresponds to a Gaussian process.<sup>[46](#page-12-0)</sup> The basic model for the distribution of multivariate Gaussian probability is the Gaussian process. It consists of a mean function, *m*, and a covariance function, *k*, which refers to a semipositive definite.

In a Gaussian process, a finite set of random variables all follow a Gaussian joint distribution, assuming a prior distribution with a mean of zero:

$$
p(f|X,\,\theta) = N\left(0,\,\sum\right) \tag{7}
$$

$$
\sum_{i,j} = k(x_i, y_i) \tag{8}
$$

where *X* is the training set,  $X = \{x_1, x_2, ..., x_i\}$  is the set of values of the unknown function  $f_i f = \{f(x_1), f(x_2),..., f(x_i)\};$   $\sum$  is the covariance matrix formed by  $k(x, x')$ ; and  $\theta$  is the hyperparameter.

The probability distribution is obtained by assuming the presence of noise that follows a Gaussian distribution, which is independent and identically distributed:

$$
p(y|f) = \mathbf{N}(f, \sigma^2 I) \tag{9}
$$

where *y* represents the set of observed values. The marginal likelihood distribution *x* is obtained based on the prior distribution and likelihood distribution equation:

$$
p(y|X, \theta) = \int p(y|f) p(y|X, \theta) \, df = \mathbf{N}\Big(0, \sum +\sigma^2 I\Big) \tag{10}
$$

Usually, by maximizing the marginal likelihood distribution to optimize hyperparameters, according to the properties of Gaussian processes, the following joint distribution exists:

$$
\begin{bmatrix} y \\ f_* \end{bmatrix}: \mathbf{N} \begin{bmatrix} 0, \begin{bmatrix} \sum +\sigma^2 I & K_* \\ K_*^T & K_{**} \end{bmatrix} \end{bmatrix} \tag{11}
$$

where  $f_*$  denotes the value of the prediction function and  $X_*$ represents the prediction input  $K^T_* = \{k(x_1, X_*)\}, k(x_2, X_*)\},$  $k(x_i, X_*)\}, K_{**} = k(X_*, X_*)$ 

The predictive distribution derived from the joint distribution can be easily determined via the following equations:

$$
p(f_*|X, y, X_*) = \mathbf{N}(\langle f_* \rangle, \text{ cov}(f_*))
$$
\n(12)

$$
\langle f_* \rangle = K_*^T \Big[ \sum + \sigma^2 I \Big]^{-1} y \tag{13}
$$

$$
cov(f_*) = K_{**} - K_*^T \Big[ \sum + \sigma^2 I \Big]^{-1} K_* \tag{14}
$$

where  $\langle f_* \rangle$  denotes the predicted mean and  $cov(f_*)$  represents the expected covariance.

Figure 4. Correlation analysis between impact factors.

*2.2.2. Collection Function.* The collection function is primarily used in the process of Bayesian optimization to determine the next most likely point of evaluation to achieve optimal model performance. A confidence-bounding strategy known as GP-UCB, proposed by Srinivas et al. $47$  for use with Gaussian processes, was applied in this study.

When maximizing the objective function, the acquisition function of the upper confidence bound (UCB) strategy was calculated via the following equations:

$$
\alpha_t(x; D_{1:t}) = \mu_t(x) + \sqrt{\beta_t} \sigma_t(x) \tag{15}
$$

where the  $\beta$  parameter balances the expectation and variance.

## **3. MODEL ESTABLISHMENT**

**3.1. Collecting and Preprocessing Data.** The experimental data used in the training of the model for the  $CO<sub>2</sub>$  and H2O/brine binary system are detailed in [Table](#page-3-0) 1. The assembled database contained 1507 IFT data points of  $CO<sub>2</sub>$ and brine systems and 210 IFT data points of impure  $CO<sub>2</sub>$ mixed with  $CH_4$  or  $N_2$  and brine systems, with a total of 1717 points covering temperatures ranging from 293.15 to 448.15 K, with pressures up to approximately 69 MPa and salinities between 0 and 5.0 mol·kg<sup>−</sup><sup>1</sup> . According to previous research, the IFT in  $CO<sub>2</sub>$ −brine systems is primarily influenced by pressure, temperature, the molar concentration of brine, and the molar fractions of methane and nitrogen.<sup>[48](#page-12-0)</sup> Correlation analysis of the data can clarify the relationships between variables, and this study adopted Pearson correlation analysis. The correlation between each influencing factor and the IFT is illustrated in Figure 4. The subsequent section includes an examination of the impact of every variable on the IFT.

There are two primary phases to the effects of pressure. In the low-pressure phase  $(p < 10$  MPa), IFT decreases significantly with the increase in pressure. This is considered the initial stage of IFT variation concerning pressure. The primary reason for this phase is the direct correlation between IFT and the density difference. As pressure increases, the

density of  $CO<sub>2</sub>$  also increases, reducing the density difference between the two phases, thereby decreasing the IFT of  $CO_2$ brine. However, once the critical pressure point is reached, known as the "pseudoplateau", IFT tends to stabilize, entering the second phase where the effect of pressure on IFT is no longer significant.<sup>[53,54](#page-12-0)</sup> Within the range of low temperature and high pressure, the IFT between  $CO<sub>2</sub>$  and brine increases with the rise in temperature. However, at high temperatures (*T* > 343 K) and low pressures  $(p < 5 \text{ MPa})$ , the IFT between carbon dioxide and brine decreases as the temperature rises. This phenomenon can be explained by the theory of Gibbs− Duhem surface energy, which posits that as the temperature increases, the kinetic energy of molecules at the interface also increases. This leads to more intense intermolecular interactions, thereby causing an increase in IFT. $37,55$  $37,55$  $37,55$  The correlation between the salt molar concentration and the outcome is shown in Figure 4. As the salinity of the brine increases, the IFT also increases accordingly. This occurs because the high salinity enhances the intermolecular forces between water molecules, requiring more energy to expand the droplet's surface, thus increasing the IFT. The impact of brines containing divalent cations on IFT is mainly more pronounced.<sup>[56,57](#page-12-0)</sup> For impurity gases, namely,  $CH_4$  and  $N_2$ , the correlation is second only to that of pressure and bivalent cations. As the content of impurity gases increases, IFT also rises, which is highly beneficial for carbon dioxide storage in saline aquifers.<sup>[58](#page-12-0)</sup> This must be taken into account by the geological sequestration of  $CO<sub>2</sub>$ .

There are some outliers in the data collected from the experiment for measurement reasons. These outliers can impact the authenticity and objectivity of the data, which in turn can affect the fitting and generalization effect of the subsequent prediction model. The data in [Table](#page-3-0) 1 were processed using the isolated forest detection approach in this study. This method mainly uses the characteristics of a high isolation degree of outliers for data screening. It calculates the isolation degree of data points by constructing a binary tree

and determines whether they are outliers according to the isolation degree. More remote data points are divided earlier in the division process. Hence, their average depth is smaller.<sup>[59](#page-12-0)</sup>

The outlier score for sample  $x$  can be calculated via the following equation:

$$
Score(x) = 2^{-E[h(x)]/c(N)} \tag{16}
$$

where  $E[h(x)]$  is the path length of sample *x*, which is calculated as follows:

$$
E[h(x)] = \frac{1}{t} \sum_{i=1}^{t} h_j(x)
$$
 (17)

where *c*(*N*) is the average path length of the tree given *N* data samples and is used to normalize *x*:

$$
c(N) = \begin{cases} 2H(N-1) - 2(N-1)/NN > 2\\ 1 & N = 2\\ 0 & N < 2 \end{cases}
$$
(18)

where  $H(X)$  is the harmonic number according to the following equation and  $\Upsilon$  is Euler's constant, approximately 0.577215:

$$
H(X) = \ln X + \Upsilon \tag{19}
$$

According to the above steps, the larger the anomaly score is, the greater the anomaly degree of the sample points. In this study, 76 sets of outlier data were eliminated after detection using isolated forests.

**3.2. BO-RF Modeling.** The flowchart for the BO-RF model is shown in Figure 5. The data set in this study was divided

Figure 5. Flowchart of the BO-RF model.

into an 8:1:1 ratio between a training set, a validation set, and a test set. The main procedure is to use the training set for model training and a hyperparameter search. A validation set was used to achieve the predetermined goal of improving the model performance. Then, a pertinent prediction of the test set based on the optimized model was carried out. In this study, a heuristic algorithm was developed to optimize the random forest (RF) model for predicting the  $CO_2$ -water/brine IFT with high integrity. These heuristic algorithms include the Sparrow Search Algorithm (SSA),<sup>[60](#page-12-0)</sup> the Particle Swarm Optimization algorithm  $(PSO)$ , and the Improved Gray

Wolf Optimization algorithm  $(IGWO)$ ,<sup>[62](#page-12-0)</sup> which are described in detail below.

**3.3. Iterative Optimization Process.** The optimization search procedure for each model is illustrated in [Figure](#page-6-0) 6. The heuristic approach iterates more slowly and virtually levels off after the 15th step to find the ideal answer, as shown in [Figure](#page-6-0) [6](#page-6-0). On the other hand, the perfect solution is roughly reached by the Bayesian optimization process in the eighth phase. The superiority of the Bayesian optimization algorithm over the heuristic method in identifying an optimal solution indicates its inherent qualities. It is also demonstrated that the Bayesian optimization method outperforms the heuristic approach in terms of efficiency. Furthermore, the Bayesian optimization algorithm yields the optimal hyperparameter for the tree as 300, the minimum leaf node for the tree as 1, and the number of selected features as 4.

#### **4. RESULTS AND DISCUSSION**

**4.1. Analysis of the Predictive Results of the Model.** The prediction results of each model are shown in [Figure](#page-6-0) 7. The closer the data point is to the 45° reference line, the greater the fitting degree between the predicted and experimental values. The figure shows that the BO-RF model has the best fitting degree compared with the other three models. [Figure](#page-7-0) 8 more intuitively shows the prediction results of the four models under the same conditions, and it can be seen from the figure that the BO-RF model has a high prediction accuracy. [Figure](#page-7-0) 8's experimental data is sourced from Reference.<sup>3</sup>

The distributions of the differences between the experimental and predicted values are displayed in [Figure](#page-7-0) 9. The results indicate that the machine learning prediction has a better fit and accuracy, with the majority of the predicted data falling within  $\pm 1.5$  mN·m<sup>-1</sup> and the remaining data being very sparse. The primary comparison of the expected and experimental values in [Figure](#page-7-0)  $9(B)$  demonstrates the remarkable accuracy of the model suggested in this study.

**4.2. Indicators for Model Evaluation.** To validate the accuracy of the model proposed in this study, several statistical parameters were calculated. The equations for each evaluation indicator are shown in [Table](#page-7-0) 2.

The statistical parameters of each model were calculated, and the results of each statistical parameter are shown in [Table](#page-8-0) [3](#page-8-0). Overall, each model tested had good predictive performance, with the BO-RF model outperforming all other predictive models, having the highest  $R^2$  (0.9729) and the lowest RMSE (1.7705) and MAPE (2.0687%). The model predictions exhibit a strong fit with the observed values.

**4.3. Comparison with Other Models.** This study compared several high-performance models with the BO-RF model to demonstrate its accuracy. It was compared with prediction methods based on genetic programming  $(GP)$ , 33 the group method of data handling  $(GMDH)<sup>42</sup>$  $(GMDH)<sup>42</sup>$  $(GMDH)<sup>42</sup>$  gene expression programming  $(GEP)$ ,<sup>[63](#page-12-0)</sup> optimizing the WNN  $model(I-WNN)$ ,<sup>[41](#page-12-0)</sup> and the correlation formula derived through GPTIPS.<sup>[54](#page-12-0)</sup> The RMSE and  $R^2$  values were chosen as the evaluation indices in this study, as shown in [Table](#page-8-0) 4. It can be concluded that the BO-RF model performs better than the other methods, with an RMSE of 1.7705 and an  $\mathbb{R}^2$  of 0.9729.

**4.4. Correlation Validation.** In this section, the relationship between various influencing factors and IFT is depicted using our model. The four panels in [Figure](#page-8-0) 10 illustrate the

<span id="page-6-0"></span>

Figure 6. Iterative optimization process.

trend of changes in IFT in relation to pressure, temperature, ionic concentration, and impurity gases, respectively. The predicted IFT by the model aligns with the trends of change in various influencing factors as discussed previously, thereby substantiating the accuracy of the model developed in this study.

## **5. IMPLICATIONS FOR CARBON STORAGE**

The primary goal of  $CO_2$ -EWR technology is to achieve enhanced water recovery and safe  $CO<sub>2</sub>$  geological storage, where site selection determines the flexibility of this scheme. Considerable numbers of sedimentary basins can be found in

<span id="page-8-0"></span>

## Table 4. Comparison of the Prediction Performance of This Model with That of Other Explicit Models

China, both on land and on the continental shelf. These basins have a wide distribution area and considerable sediment thickness, with the widespread occurrence of brine layers suitable for  $CO<sub>2</sub>$  sequestration, especially in the Xinjiang region.<sup>[11](#page-11-0)</sup> According to previous studies, there are four primary

forms of sequestration: structural, residual (capillary), solubility, and mineralization trapping.<sup>[16](#page-11-0)−[19](#page-11-0)</sup> The widespread existence of saline aquifers is suitable for  $CO_2$ -EWR projects, and assessing the storage capacity of injection sites is crucial. This study evaluated capillary trapping in the Tarim Basin in Xinjiang.

During the geological storage of  $CO<sub>2</sub>$ , as mentioned in introuduction section, leakage occurs when the pressure difference between  $CO<sub>2</sub>$  and the saline system exceeds the breakthrough pressure. Due to the buoyancy effect of supercritical  $CO<sub>2</sub>$ , buoyancy becomes the driving force for  $CO<sub>2</sub>$  leakage. As mentioned in [eq](#page-1-0) 1, leakage occurs when the pressure difference between  $CO<sub>2</sub>$  and the saline system exceeds the breakthrough pressure. Due to the buoyancy effect of supercritical  $CO_2$ , buoyancy becomes the driving force for  $CO_2$ leakage. To guarantee the airtightness and safety of the stored

Figure 10. Prediction of IFT Influencing factors A: Salinity at *T* = 323.15 K with no impurities, B: Temperature by keeping salinity 0.98 mol/kg with no impurities, C: Presence of Impurities at  $T = 333.15$  K, and D: Salt type at  $T = 344.15$  K with no impurities.

 $CO<sub>2</sub>$ , its buoyancy must not exceed the capillary pressure of the largest pore. Assuming that the height of the reservoir occupied by  $CO<sub>2</sub>$  stored in the sedimentary layer is  $h$ , the magnitude of the buoyancy force acting on  $CO<sub>2</sub>$  is (*ρ*water−*ρCO*<sup>2</sup> )*gh*. If the variation in the contact angle with temperature and pressure is ignored, the threshold capillary pressure is  $P_{ce} = 2\sigma/R$ . When the maximum height of CO<sub>2</sub> storage is denoted as  $H$ , then:<sup>6</sup>

$$
H = \frac{2\sigma}{(\rho_{\text{water}} - \rho_{\text{CO}_2})gR}
$$
\n(20)

where  $\sigma$  is the IFT between  $CO_2$  and brine;  $\rho$  is the density, with the subscripts water and  $CO<sub>2</sub>$  being the density of brine and carbon dioxide, respectively; *g* is the acceleration due to gravity; and *R* is the size of the largest pore or small seam in the cap layer. Here, due to the lack of contact angle data, we assume that the brine is an excellent wetting fluid; therefore, the contact angle is not considered in calculating the  $CO<sub>2</sub>$ storage capacity in the saline aquifer.<sup>55,[64](#page-12-0),[65](#page-12-0)</sup>

Thus, the mass of  $CO<sub>2</sub>$  per unit of reservoir area can be expressed as:<sup>[42](#page-12-0)</sup>

$$
MCO_2 = \frac{2\sigma\rho CO_2 \phi (1 - S_{\text{swirr}})}{(\rho_{\text{water}} - \rho_{\text{CO}_2}) gR}
$$
(21)

where  $x$  is the porosity of the brine layer in the sedimentary basin and *y* is the residual water saturation.

Recently, a number of approaches have been proposed for evaluating  $CO<sub>2</sub>$  sequestration capacity of the reservoir. The US Department of Energy<sup>66</sup> and CSLF have suggested evaluation methods; however, these methods are assessed on a macroscopic level, and intermolecular interactions are not taken into consideration. Thus, the Xinjiang region of China's Tarim Basin was selected as the injection site, and eq 21 was applied to estimate the  $CO<sub>2</sub>$  sequestration capacity of this basin at various depths in this study. The BO-RF model presented in this study was used to determine the IFT for the  $CO_2$ −brine system in eq 21, while the density of the fluids can be obtained via the NIST Web site [\(http://www.ap1700.com/](http://www.ap1700.com/)). The values of the remaining parameters are detailed in Table 5.

#### Table 5. Values of Relevant Parameters

Due to the variation in the concentration of saltwater in the selected basin, concentrations of 0.98 mol/kg and 2.97 mol/kg were used to simulate the influence of salinity on the estimation of the  $CO<sub>2</sub>$  storage capacity. In contrast to other scholars, <sup>[55](#page-12-0),[65,67](#page-12-0)</sup> this study considered the seawater concentration and assessed sequestration between depths of 800 and 5000 m. The basin has a greater  $CO<sub>2</sub>$  storage capacity when CO2 is injected approximately 1,000−2,000 m below the surface. The same observation was made by Chiquet et al.<sup>64</sup> The amount of sequestered  $CO<sub>2</sub>$  increases, although at a prolonged rate, until the depth of sequestration approaches 2500 m, as illustrated in [Figure](#page-10-0) 11. *R* is a constant in this study. However, with increasing injection depth, the  $CO<sub>2</sub>$  sequestered increases in total. It can also be seen from [Figure](#page-10-0) 11 that the higher the concentration in the brine layer is, the more  $CO<sub>2</sub>$ can be sequestered in the reservoir. As illustrated in [Figure](#page-8-0)

 $10(B)$  $10(B)$ , IFT between  $CO<sub>2</sub>$  and brine increases with rising temperature, resulting in the increase of the  $CO<sub>2</sub>$  sequestered capacity of the reservoir. The burial depth had a limited influence on the  $CO<sub>2</sub>$  storage capacity. This may be because at deeper storage altitudes, the density differences between reservoir brine and  $CO<sub>2</sub>$ , where it is in a supercritical state, are lower, resulting in a smaller change in IFT, which ultimately leads to a little change in  $CO<sub>2</sub>$  sequestration capacity of the reservoir. On the other hand, this is also related to wettability. Although brine is assumed to be an excellent wetting fluid in the calculation of  $CO<sub>2</sub>$  storage capacity in saline aquifers, thereby not considering the impact of the wettability remains an important parameter for  $CO<sub>2</sub>$  geological sequestration. It determines the affinity between  $CO<sub>2</sub>$  and the reservoir rock fluids, affecting the distribution and migration of  $CO<sub>2</sub>$  within the reservoir. Under water-wet conditions, the rock surface tends to bind more readily with water molecules, while  $CO<sub>2</sub>$  is more likely to form a continuous nonwetting phase, which aids in capturing and storing  $CO<sub>2</sub>$ .<sup>[68](#page-12-0)</sup> Temperature, pressure, salinity, salt type, and impurities gases impact wettability. Additionally, wettability influences the solubility of  $CO<sub>2</sub>$  in reservoir water, thereby affecting the efficiency of dissolution trapping.<sup>[69](#page-12-0),[70](#page-12-0)</sup> IFT and wettability are significant factors affecting the quantity and safety of  $CO<sub>2</sub>$  storage in saline aquifers and should be given considerable attention during the estimation of the the  $CO<sub>2</sub>$  sequestered capacity of the reservoir.

## **6. CONCLUSIONS**

In this study, a database of 1717 sets of experimental values was established, covering the temperature range of 293.15 to 448.15 K, a pressure of up to 69 MPa, and a concentration of salinities from 0 to 5.0 mol·kg<sup>-1</sup>, basically covering the geological environment conditions of the storage of  $CO<sub>2</sub>$  saline aquifers. The database was divided into a training set, a verification set, and a test set, accounting for 8:1:1, respectively. In this study, three combined models, the SSA-RF, PSO-RF, and IGWO-RF models, were established for comparison with the BO-RF model. In addition, the IFT was used as an input parameter to evaluate the carbon sequestration potential of the Tarim Basin in China. On the basis of results, the following conclusions can be drawn:

1. The precision of the BO-RF model made in this study is nicer than other heuristic algorithms and displays good results in foretelling the IFT of carbon dioxide in brine. The BO-RF model shows the lowest RMSE (1.7705) and MAPE  $(2.0687%)$ , and the highest R<sup>2</sup> value  $(0.9729)$ . This study also selected other excellent ML models for comparison. The results revealed that the BO-RF model has the best performance.

2. The model was statistically sound since the use of isolated forests assisted in identifying outliers, which accounted for just 4% of the total data set. At the same time, the analysis in this study shows the critical factors that have an influence on the magnitude of the IFT in the  $CO<sub>2</sub>$ -brine system, and these variables have been ranked in order of importance: pressure > bivalent cation molality  $>$  mole fraction of CH<sub>4</sub>  $>$  mole fraction of  $N_2$  > temperature > monovalent cation molality. It was found that pressure had the greatest effect, and the molar concentration of monovalent cations had the least effect on the IFT.

3. With increasing injection depth, the  $CO<sub>2</sub>$  concentration also decreases, and eventually, the  $\mathrm{CO}_2$  sequestered capacity of

<span id="page-10-0"></span>

Figure 11. Variation curve of  $CO<sub>2</sub>$  sequestration with burial depth per unit basin area.

the reservoir  $CO<sub>2</sub>$  concentration increases in total. However, the burial depth had a limited influence on the  $CO<sub>2</sub>$  storage capacity due to the phase change of the  $CO<sub>2</sub>$ . It has also been found that if the salt content of the water increases, the carbon storage potential will also increase. However, the cost of  $CO<sub>2</sub>$ storage in this project increased with increasing injection depth, which led to a decrease in its feasibility. Therefore, the storage depth should be comprehensively considered in the site selection process, and the physical properties of reservoir fluids, especially the salinity, should be sampled and analyzed to obtain the injection site and storage depth that are most suitable for carbon storage projects.
