Background: The role of antithrombotic chemoprophylaxis in prevention of venous thromboembolism (VTE) in laparoscopic surgery for gastric and colorectal malignancies is unknown. This study compared the addition of enoxaparin following intermittent pneumatic compression (IPC) with IPC alone in patients undergoing laparoscopic surgery for gastrointestinal malignancy.

Methods: In this multicentre RCT, eligible patients were older than 40 years and had a WHO performance status of 0 or 1. Exclusion criteria were prescription of antiplatelet or anticoagulant drugs and history of VTE. Patients were allocated to IPC or to IPC with enoxaparin in a 1 : 1 ratio. Stratification factors included sex, location of cancer, age 61 years and over, and institution. Enoxaparin was administered on days 1–7 after surgery. Primary outcome was VTE, evaluated by multidetector CT on day 7.

Results: Of 448 patients randomized, 208 in the IPC group and 182 in the IPC with enoxaparin group were evaluated. VTE occurred in ten patients (4.8 per cent) in the IPC group and six (3.3 per cent) in the IPC with enoxaparin group ($P = 0.453$). Proximal deep vein thrombosis and/or pulmonary embolism occurred in seven patients (3.4 per cent) in the IPC group and one patient (0.5 per cent) in the IPC with enoxaparin group ($P = 0.050$). All VTE events were asymptomatic and non-fatal. Bleeding occurred in 11 of 202 patients in the IPC with enoxaparin group, and one patient needed a transfusion. All bleeding events were managed by discontinuation of the drug.

Conclusion: IPC with enoxaparin after laparoscopic surgery for gastric and colorectal malignancies did not reduce the rate of VTE. Registration number: UMIN000011667 (<https://www.umin.ac.jp/>).

Introduction

Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), is one of the most critical postoperative complications. Between 15 and 40 per cent of surgical patients develop VTE, and 0.8 per cent of those patients will develop fatal PE without receiving antithrombotic prophylaxis¹. Meta-analyses^{2–5} of RCTs have shown that antithrombotic prophylaxis reduces the incidence of VTE.

According to the VTE risk score after surgery^{6,7}, the guidelines of the American College of Chest Physicians (ACCP)⁸ and the American Society of Clinical Oncology⁹ recommend the use of antithrombotic chemoprophylaxis after major abdominal cancer surgery. For laparoscopic surgery, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES)¹⁰ recommends following the ACCP guidelines. SAGES also mentions the need for further studies to establish antithrombotic

chemoprophylaxis for VTE after laparoscopic surgery, because there was a statistically significant reduction in the risk of VTE after laparoscopic compared with open surgery¹¹.

The aim of this study was to assess the additional effect of antithrombotic chemoprophylaxis with enoxaparin to prevent VTE in patients undergoing laparoscopic surgery for gastrointestinal cancer.

Methods

In this multicentre RCT, patients with gastric or colorectal cancer scheduled for laparoscopic surgery in 15 regional Japanese hospitals in Hokkaido prefecture between October 2013 and October 2017 were eligible for inclusion. All hospitals were certified facilities of the Japan Surgical Society and the Japanese Society of Gastroenterological Surgery, and all surgeons were board-certified in gastroenterology and/or qualified surgeons of the Japan Society for Endoscopic Surgery. Inclusion criteria were patients older than 40 years with WHO performance status 0 or 1, who agreed to participate in the study. Exclusion criteria were a history of heparin-induced thrombocytopenia or heparin hypersensitivity, acute bacterial endocarditis, creatinine clearance below 50 ml/min, severe hepatic dysfunction (Child grade C), weight less than 40 kg, pregnancy, prescription of antiplatelet or anticoagulant drugs, history of venous thromboembolic disease within 1 year, history of hypersensitivity for iodinated contrast agent, presence of central venous catheter, treatment with oestrogen or progesterone within 4 weeks of the operation, and radiotherapy or chemotherapy within 2 weeks of surgery. Preoperative examination by ultrasonography or CT to rule out the presence of DVT/PE was performed in patients with a preoperative D-dimer value of 1.0 µg/ml or above. Patients who met these inclusion and exclusion criteria were randomized after registration.

Patients whose condition changed while waiting for surgery and who then met the exclusion criteria were excluded. Patients who met any of the following criteria after surgery were excluded from evaluation: patients not treated, those with peritoneal dissemination, conversion to open surgery, haemoglobin level below 9.5 g/dl, alanine or aspartate aminotransferase values more than 2.5 times the normal values for the facility, total bilirubin concentration above 3.0 mg/dl, oxygen saturation less than 90 per cent, incomplete haemostasis (defined by persistent bleeding from abdominal drain or gastrointestinal tract), and withdrawal of consent. In addition, patients who were withdrawn from the study because of adverse events and complications were excluded. The final VTE evaluation was

carried out for patients who completed the study protocol. Patients excluded from the study after surgery were treated without enoxaparin. The study was conducted in an open-label fashion.

Ethical approval

The study was performed with the approval of the Internal Review Board on ethical issues of Hokkaido University Hospital and participating sites. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee, and with the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. Written informed consent was obtained from all individual participants included in the study. The study was registered at the UMIN Clinical Trials Registry System (<https://www.umin.ac.jp/ctr/>; ID UMIN000011667).

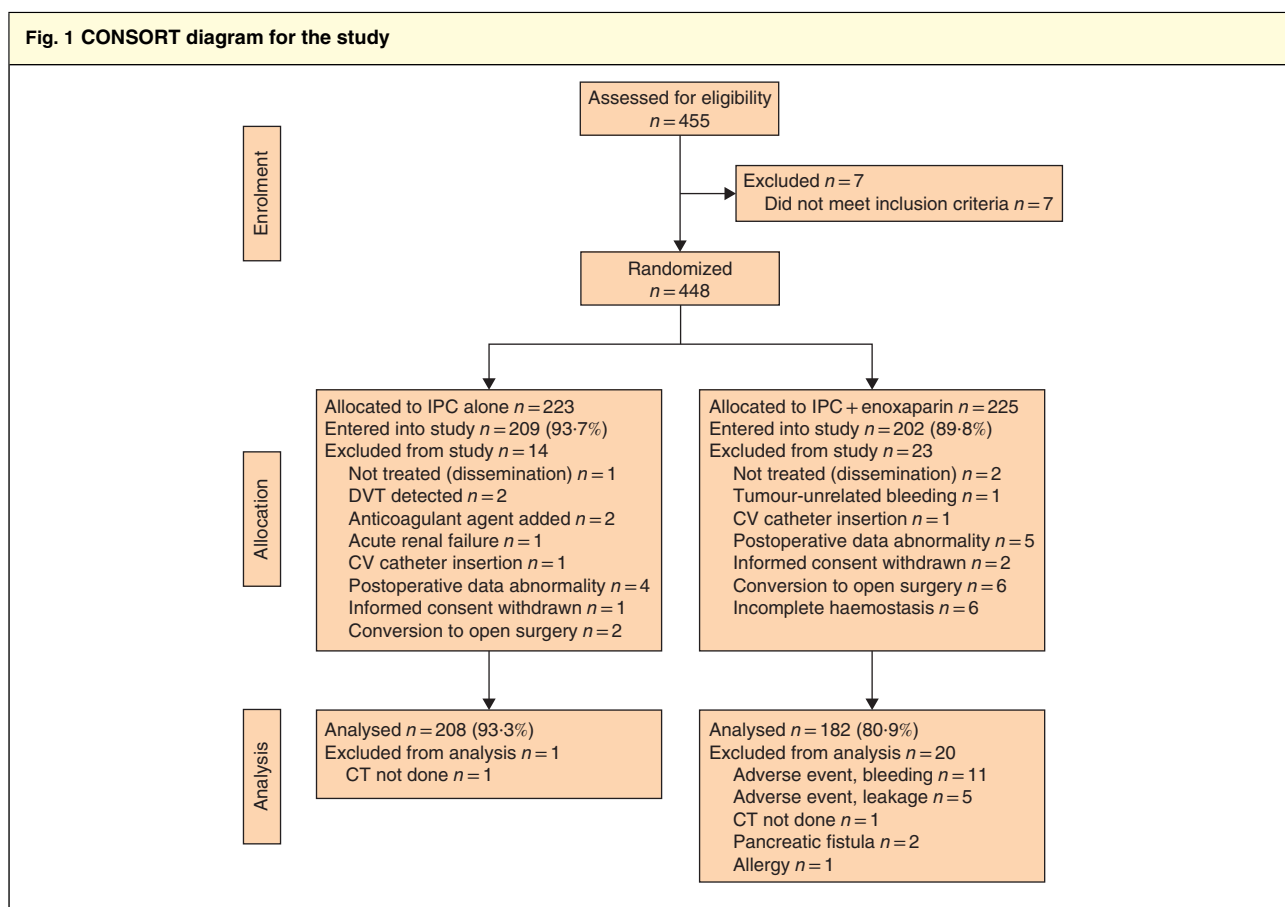

Randomization

Physicians designated by each hospital registered the patients, and central computer-generated randomization was performed by the research coordinators of Hokkaido University Hospital's Clinical Research and Medical Innovation Centre. Patients were allocated to intermittent pneumatic compression (IPC) or to IPC with enoxaparin in a 1:1 ratio at least 1 day before surgery. Stratification factors included sex, location of cancer (stomach, colon or rectum), age 61 years or more, and institution.

Blinding was considered to be impossible in this study.

Study procedures

All operations were performed by standard multiport laparoscopic surgery with pneumoperitoneum pressure from 12 to 8 mmHg. The lithotomy position was done for the colorectal operation, and linear and circular staplers were used for gastrointestinal anastomoses. The postoperative recovery protocol was according to enhanced recovery after surgery (ERAS) principles. The IPC system was applied to both legs after induction of anaesthesia and before patient positioning. Calf-length sleeves were used. IPC was continued until leaving the bed on the first postoperative day (POD1). Enoxaparin was administered from 24 h after surgery (subcutaneous injection of 2000 units twice daily on POD1–7). In patients in the IPC with enoxaparin group who also had epidural anaesthesia, administration of enoxaparin was discontinued for 12 h before and after removal of the epidural tube.

IPC, intermittent pneumatic compression; DVT, deep vein thrombosis; CV, central venous.

Outcome

The primary outcome was VTE (DVT and PE), both symptomatic and asymptomatic, diagnosed by multidetector CT on POD7. DVT located below the knee and confined to the calf veins was defined as distal DVT, and that located in the popliteal, femoral or iliac veins was defined as proximal DVT. The radiologist in each hospital evaluated the occurrence of VTE with no information on patient allocation.

The secondary outcome was bleeding that occurred by POD7. Postoperative bleeding was classified as major or minor, defined according to the International Society on Thrombosis and Haemostasis criteria¹². Major bleeding was defined as intracranial, retroperitoneal or clinically overt haemorrhage associated with a decrease in the haemoglobin level of more than 20 g/l, transfusion of two or more units of packed cells, or need for surgical intervention. Minor bleeding was defined as clinically relevant non-major bleeding associated with medical intervention. All bleeding events were reviewed by the

Internal Review Board at each participating site. Patients with adverse events and complications by POD7 that led to study discontinuation were excluded from the final evaluation.

Data collection

Study data, including patient characteristics, medical history, laboratory data, cancer type and staging, surgical information and outcome, and VTE events, were transferred to the central data collection centre.

Sample size calculation

The incidence of VTE for high-risk gastrointestinal surgery is 20–25 per cent¹, and laparoscopic surgery reduces the incidence by about one-half¹¹. The estimated risk of VTE was therefore 10.0 per cent in the IPC group. The estimated risk of VTE in the IPC plus enoxaparin group was 2 per cent¹³, implying an 8 per cent reduction.

Table 1 Patient demographics and clinical details of randomized and treated patients

With an α of 0.05 and β of 0.10, 368 patients had to be evaluable in the study. The anticipated dropout rate due to adverse events in either group was 20 per cent. Therefore, 450 patients had to be recruited for the study.

Statistical analysis

Statistical analysis was performed using JMP® Pro 13.0.0 for Windows® (SAS Institute, Cary, North Carolina, USA). Categorical data were compared with the χ^2 test,

Table 2 Venous thromboembolism in evaluable patients

	Total (n = 390)	IPC alone (n = 208)	IPC with enoxaparin (n = 182)	P*
Overall VTE	16 (4.1)	10 (4.8)	6 (3.3)	0.453

Proximal DVT or PE	8 (2.1)	7 (3.4)	1 (0.5)	0.050

Values in parentheses are percentages. IPC, intermittent pneumatic compression; VTE, venous thromboembolism; DVT, deep vein thrombosis; PE, pulmonary embolism. * χ^2 test.

and continuous or ordinal data using the Mann–Whitney *U* test. $P < 0.050$ (two-sided) was considered to denote statistical significance. The analysis was not done according to the intention-to-treat principle.

Results

Of 455 patients who were offered participation in the study, 448 were registered and randomized. After post-randomization exclusion, 209 patients remained in the IPC group and 202 in the IPC with enoxaparin group (Fig. 1). Following exclusion for postoperative complications, 208 and 182 patients respectively in these two groups remained in the study for evaluation of the primary endpoint. Patient demographics and clinical characteristics of evaluable patients in the two groups were comparable (Table 1). The surgical characteristics (surgical procedure, cancer type, cancer stage according to the TNM classification, duration of surgery, and use of the lithotomy position during surgery) of evaluable patients showed no statistical differences between the two groups.

Thromboembolic events

All VTE events were asymptomatic and not fatal. Ten of the 208 patients in the IPC group had a VTE event (4.8 (95 per cent c.i. 2.6 to 8.6) per cent), compared with six of the 182 patients in the IPC with enoxaparin group (3.3 (1.5 to 7.0) per cent) ($P = 0.453$) (Table 2).

Bleeding complications and adverse events

All 208 patients in the IPC group had an uneventful course and completed the study. Bleeding complications were observed in 11 of 202 patients (5.4 (95 per cent c.i. 3.1 to 9.5) per cent) in the IPC with enoxaparin group. Ten patients had minor bleeding and one patient had major bleeding requiring a blood transfusion. Bleeding sites included blood loss via the abdominal drain (3 patients), subcutaneous bleeding (4) and anastomosis bleeding (4);

bleeding events occurred a mean(s.d.) of 3.5(1.4) days after surgery. Haemostasis was obtained in all patients with drug discontinuation, and none required an additional intervention. Bleeding did not lead to death.

During follow-up of up to 30 days after surgery, no signs of symptomatic VTE were seen. In addition to the five patients (2.5 per cent) with anastomotic leakage in the IPC with enoxaparin group (Fig. 1), surgical-site infection (SSI) occurred in five (1.3 per cent) of 385 evaluable patients (3 superficial and 2 organ/space SSI).

Discussion

Compared with IPC alone, IPC with postoperative administration of enoxaparin for 1 week did not significantly reduce VTE after laparoscopic surgery for gastric or colorectal malignancy.

The incidence of VTE after laparoscopic surgery is lower than that after open surgery¹¹, but methods for diagnosis of VTE vary from examination of only symptomatic cases to examination with active screening of lower-limb ultrasonography and/or venography. In the literature, the incidence of VTE after laparoscopic gastric surgery, including bariatric surgery, ranges from 0 to 19.4 per cent^{14–18}, and that after laparoscopic colorectal surgery ranges from 0.8 to 17.1 per cent^{18–25}. By active screening with duplex ultrasonography and either ventilation–perfusion scanning or CT angiography in injured patients, the rate of DVT increases tenfold and the rate of PE almost fivefold²⁶. Multidetector CT has high diagnostic accuracy for PE and DVT, with a sensitivity of 90 per cent and specificity of 95 per cent for PE, and values of 97 and 100 per cent respectively for DVT^{27,28}.

In the present study, the observed incidence of diagnosis of perioperative VTE by multidetector CT in patients whose operation was completed laparoscopically and who had no serious adverse events during the first week was lower than expected. Sakon and colleagues¹³ reported that the incidence of VTE diagnosed by active screening of lower-limb venography after major abdominal surgery was

19.4 per cent with no antithrombotic chemoprophylaxis. Symptomatic VTE had not occurred. Laparoscopic *versus* open surgery and mobilization of patients according to an ERAS protocol may have influenced the incidence of VTE in the IPC-alone group.

Additional morbidity associated with enoxaparin was limited. This study was not powered to detect a difference in proximal venous thrombosis and PE. In patients with additional risk factors for VTE, including obesity and advanced cancer, chemoprophylaxis should be considered, despite the negative findings in this study.

This study has some limitations. The primary endpoint was not evaluated in all patients who were randomized owing to conversion to open surgery and complications. Nothing can be concluded regarding the efficacy of thrombotic prophylaxis in these patients, and their exclusion may have influenced the results. The overestimated incidence of VTE with no thrombotic prophylaxis in laparoscopic surgery for colorectal and gastric cancer in the study protocol led to a study that was underpowered to assess a statistically significant difference between groups. Caution should be exercised in generalizing the results of this study to the rest of the world, as all patients were Asian, whose population-wide VTE incidence is approximately 15–20 per cent of the levels recorded in Western countries²⁹. In addition, the mean BMI of patients was low, and early-stage cancer was common.
