Original Article

Background: Xanthelasma palpebrarum (XP) is a benign periorbital lesion. The relationship between xanthelasma lesion size and serum cholesterol levels has been poorly studied. In this study, we investigated this relationship in the context of the clinical etiology of XP.

Methods: We retrospectively reviewed medical records and pathology reports of all patients treated for XP at our hospital between June 2014 and June 2021; the data were used to analyze lesion size, underlying disease, serum cholesterol, and disease recurrence.

Results: The mean values for patient age, serum cholesterol, and lesion size were 53.0 years, 235.0 mg/dL, and 69.2 mm², respectively. XP mainly occurred in women (64.7%); furthermore, the incidence of XP and lesion size was greatest among patients in their 5th decade of life (41.2%). There was no statistically significant relationship between xanthelasma lesion size and serum cholesterol level.

Conclusion: This study compared lesion size with various clinical features in XP patients. In patients who underwent surgery for XP, serum cholesterol levels tended to be higher than those in the general population. However, the trend between the size of XP and serum cholesterol level was unclear. Therefore, if a patient with XP visits the hospital for surgery, it is recommended to check the lipid profile to confirm underlying dyslipidemia regardless of the size.

Abbreviations: LDL, low-density lipoprotein; XP, xanthelasma palpebrarum

Keywords: Dyslipidemia / Foam cells / Hypercholesterolemia / Xanthoma

INTRODUCTION

Xanthelasma palpebrarum (XP) is a benign periorbital tumor. The term xanthelasma was first proposed by the 19th-century English surgeon and dermatologist, Sir Erasmus Wilson, derived from the Greek words “Xanthos” (yellow) and “Elasma” (beaten metal plate) [1]. As the name suggests, XP presents as yellowish papules or plaques on the eyelids.

The prevalence of XP is approximately 1.1% in women and 0.3% in men [2]. XP is known to be associated with hypercholesterolemia, and reports indicate that approximately 50% of patients diagnosed with XP also have hypercholesterolemia [2]. Histologically, xanthelasmas are composed of foam cells, which are lipid-laden histiocytes [3]. These foam cells accumulated mainly in the upper reticular dermis layer near the capillaries, appearing as yellowish skin lesions. Considering the pathogenesis, leakage of low-density lipoprotein (LDL) from the capillaries is an important aspect of the disease etiology [3,4]; mechanical movement and friction, heat, and inflammatory responses accelerate the leakage of LDL. These factors are prevalent around the eyelids, explaining the higher incidence of xanthelasma appearance compared other parts of the body [5].

Many studies have studied the clinical characteristics of xanthelasma, however, few studies have investigated the size of XP

and the relationship between other clinical features. Therefore, in this study, we analyzed the size of XP lesions and their clinical characteristics to examine the relationship between elevated serum cholesterol levels and XP size.

METHODS

Study design and patients

We conducted a retrospective chart review of patients diagnosed with XP, who underwent surgery between August 2014 and September 2021. The participants of this study were patients with suspected XP lesions, confirmed by biopsy, in whom serum cholesterol levels were measured preoperatively. A total of 41 patients were clinically suspected of XP and underwent surgery. Four patients were excluded from the analysis because the pathologic diagnosis was not made. Three of the remaining 37 patients were excluded from the study because their serum cholesterol levels were not measured. A total of 34 patients were included in the analysis.

Evaluation of outcomes

We investigated the patient's lesion size and location, serum total cholesterol level, underlying disease, and XP recurrence. Serum cholesterol levels were divided into normal (< 200 mg/dL), intermediate (200–239 mg/dL), and hypercholesterolemia (≥ 240 mg/dL) groups. The area of the xanthelasma was assumed to have an elliptical shape and was calculated using the long (a) and short axis (b) measured preoperatively. If there were multiple lesions, the size of each lesion was added (Fig. 1).

$$\text{Total lesion size of XP} = \sum_i \pi \times \frac{a_i}{2} \times \frac{b_i}{2} = \sum_i \frac{\pi a_i b_i}{4}$$

The lesions were classified according to the grading system proposed by Lee et al. in 2013 [6]. Lesions of grade I were limited to the upper eyelid, grade II involved the medial canthus,

Fig. 1. Xanthelasma palpebrarum-lesion size estimation methodology. The lengths of the major (a_1 and a_2) and minor (b_1 and b_2) axes were measured assuming the most similar ellipse, including that of the lesion. Based on this measurement, the sum of the ellipse areas was calculated to estimate the size of the lesion.

grade III affected both eyelids on the medial side, and grade IV involved both medial and lateral sides of the upper and lower eyelids (Fig. 2).

Operative technique

All patients underwent xanthelasma excision under local anesthesia. A simple excision of the lesion in an elliptical shape was generally performed to prevent eyelid deformities. In cases with multiple lesions, each lesion was excised through a different incision (Fig. 3). If the lesion had a diffuse distribution, a local flap or upper blepharoplasty was performed to prevent eyelid

Fig. 2. Xanthelasma grading system. (A) Grade I is limited to the upper eyelid; (B) grade II involves the medial canthus; (C) grade III affects both eyelids on the medial side; and (D) grade IV involves both the medial and lateral sides of the upper and lower eyelids.

deformity (Fig. 4). Invasion of the xanthelasma into the orbicularis oculi prompted excision of the affected muscle section. The skin was repaired using black silk 7-0 sutures.

Fig. 3. A 59-year-old man with xanthelasma palpebrarum (grade IV). The patient was diagnosed with hypercholesterolemia and received lipid-lowering therapy. Lesions involving the upper and lower eyelids were observed on both sides and each was removed separately. (A) Preoperative and (B) postoperative clinical images.

Fig. 4. A 49-year-old woman with xanthelasma palpebrarum (grade I). The patient reported that she had not been diagnosed with any disease. However, her total serum cholesterol level before surgery was 222 mg/dL, which led to her distribution in the intermediate cholesterol level group. Grade I lesions were present on both sides, and upper blepharoplasty was performed to prevent eyelid deformities. (A) Preoperative and (B) postoperative clinical images.

Statistical analysis

Continuous variables between groups were compared using Mann-Whitney *U* and Kruskal-Wallis tests. In addition, the one-sample Wilcoxon signed-rank test was used to compare the patients’ average serum cholesterol levels with those of the general population. Statistical significance was set at *p* < 0.05. All analyses were performed using IBM SPSS Statistics for Windows (version 25.0; IBM Corp., Armonk, NY, USA).

RESULTS

Of the 34 patients analyzed, 12 were men (35.3%) and 22 were women (64.7%). The patients’ age at the time of surgery ranged from 34 to 74 years, with a mean age of 53.0 years. Grade I lesions were the most common (52.9%), followed by grades III (17.6%), II (14.7%), and IV (14.7%). Regarding the laterality of the lesion, 10 patients (29.4%) showed unilateral lesions and 24 patients (70.6%) showed bilateral lesions (Table 1).

Table 1. Patient characteristics

Characteristics	Value
Age (yr)	53.0 ± 8.2
< 50	12 (35.3)
50–59	14 (41.2)
≥ 60	8 (23.5)
Sex	
Male	12 (35.3)
Female	22 (64.7)
Serum cholesterol level	
Normal (< 200 mg/dL)	4 (11.8)
Intermediate (200–239 mg/dL)	17 (50.0)
Hypercholesterolemia (≥ 240 mg/dL)	13 (38.2)
Xanthelasma grade	
Grade I	18 (52.9)
Grade II	5 (14.7)
Grade III	6 (17.6)
Grade IV	5 (14.7)
Laterality	
Unilateral	10 (29.4)
Bilateral	24 (70.6)
Past medical history	
Diabetes	1 (2.9)
Hypertension	2 (5.9)
Recurrence	6 (17.6)
Body mass index (kg/m ²)	23.9 ± 3.3
Size (mm ²)	69.2 ± 64.4
Total serum cholesterol (mg/dL)	235.0 ± 38.6

Values are presented as mean ± SD or number (%).

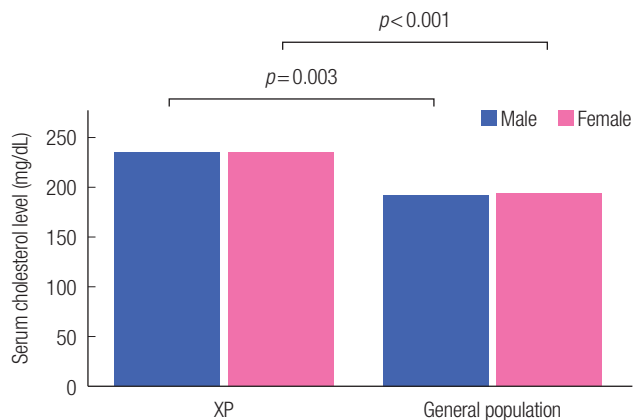

Fig. 5. Comparison of serum cholesterol levels in xanthelasma palpebrarum (XP) patients and the general population. Regarding serum cholesterol levels, the mean serum cholesterol level in all patients was 235.0 mg/dL. When the XP patients were classified by sex, serum cholesterol level was found to be 234.8 mg/dL in men and 235.2 mg/dL in women, which was significantly higher than the average cholesterol concentration of Korean adults, 192 mg/dL in men and 194 mg/dL in women, respectively (one-sample Wilcoxon signed-rank test, $p=0.003$, $p<0.001$, respectively).

The mean serum cholesterol level in all patients was 235.0 mg/dL. When the XP patients were classified by sex, serum cholesterol level was found to be 234.8 mg/dL in men and 235.2 mg/dL in women. As reported by a paper published in 2021 [7], the average cholesterol level in Korean adults was 192 mg/dL in men and 194 mg/dL in women. In this study, the serum cholesterol level was found to be higher in both men and women compared to the Korean general population ($p=0.003$ and $p<0.001$) (Fig. 5).

XP size was compared according to sex, grade, laterality, and serum cholesterol levels. The mean lesion was 69.2 mm². According to the serum cholesterol level, the normal cholesterol group was largest size (87.0 mm²), followed by the intermediate group (69.8 mm²) and hypercholesterolemia group (63.1 mm²). However, the difference was not statistically significant. In addition, there were no significant differences in xanthelasma grade, age, or sex. The only significant difference was found in laterality, where bilateral lesions (87.8 mm²) were larger than unilateral lesions (24.7 mm²) (Table 2, Fig. 6).

DISCUSSION

This was a retrospective study investigating the relationship between XP size and other clinical characteristics. As in previous studies, XP was prevalent in middle-aged women [2,8]. In addition, grade I lesions involving only the upper eyelid were the most common, with the lesions coinciding on both sides. In this study, surgical excision was performed in all xanthelasma

Table 2. Size analysis of the xanthelasma palpebrarum

Variable	Size of xanthelasma (mm ²)	p-value
Age (yr)		0.116 ^{a)}
< 50	67.2 ± 54.2	
50–59	87.6 ± 78.8	
≥ 60	40.2 ± 41.7	
Sex		0.168 ^{b)}
Male	95.8 ± 87.2	
Female	54.8 ± 43.7	
Serum cholesterol level		0.971 ^{a)}
Normal (< 200 mg/dL)	87.0 ± 87.4	
Intermediate (200–239 mg/dL)	69.8 ± 72.0	
Hypercholesterolemia (≥ 240 mg/dL)	63.1 ± 49.2	
Xanthelasma grade		0.431 ^{a)}
Grade I	66.8 ± 71.6	
Grade II	63.2 ± 46.7	
Grade III	44.2 ± 25.8	
Grade IV	114.0 ± 76.6	
Laterality		< 0.001 ^{b),c)}
Unilateral	24.7 ± 16.1	
Bilateral	87.8 ± 68.0	

Values are presented as mean ± SD.

patients. Since the eyelids are the important structure that protects and lubricates the globes and cornea, it is essential to preserve their structure [9,10]. In most cases, simple excision followed by primary closure was enough. However, if the lesion had diffuse distribution, we performed local flap techniques or upper blepharoplasty in order to avoid eyelid deformity [4,6,11].

In papers published in Western countries, approximately 50% of patients with XP are associated with hypercholesterolemia [2]. Similarly, in a study conducted in Taiwan, dyslipidemia was present in 50% of patients [8]. This study found that approximately 38.2% of patients had hypercholesterolemia in the preoperative evaluation. This result is estimated to be higher than the prevalence of 20.7% in the general population of Korea [7].

Although there was no statistically significant difference in the size analysis of patients with XP, several trends could be identified. Most patients with XP ranged from 50 to 59 years of age, and the lesion size was the most extensive among these patients. XP is a more prevalent disease in women, but paradoxically, its size tends to be larger in men. It could be explained that women are more sensitive to facial aesthetics than men, so they are apt to come to the hospital for surgery.

A limitation to the generalizability of this study is that the sample size is relatively small and that it was conducted only at

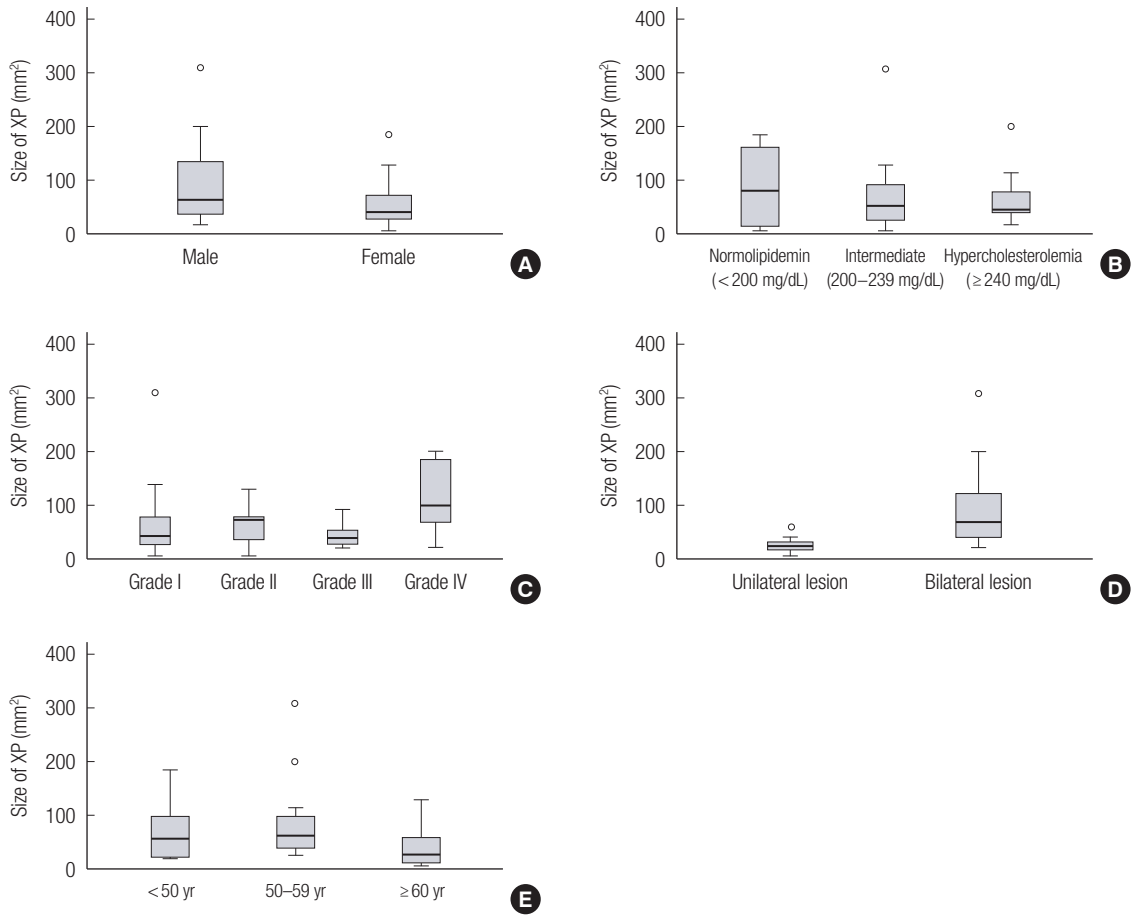

Fig. 6. Comparison of serum cholesterol levels according to clinical characteristics. The size of the xanthelasma palpebrarum (XP) lesions of the patients was analyzed by dividing it into sex, total serum cholesterol, grade, laterality, and age. There were no statistically significant differences in sex (A), serum cholesterol concentration (B), grade (C), or age (E). Meanwhile, the bilateral lesion group had a significantly larger area when analyzed according to laterality (D).

a single center. Therefore, a further large-scale study is needed. Another limitation was that other lipid profiles, including LDL cholesterol, were not examined. Meanwhile, in this study, comparing the serum cholesterol level with the general population requires careful interpretation. Since the analysis was performed on patients who underwent surgical treatment at the plastic surgery department, the possibility of selection bias should be considered. Also, in the case of patients taking lipid-lowering medications, serum cholesterol may be lowered by the drug, so it is necessary to analyze them separately to account for this discrepancy. However, this study is limited in that it could not be implemented due to the omission of records, possibly leading to confounding bias.

This study compared lesion size with various clinical features in XP patients. In patients who underwent surgery for XP, blood cholesterol levels tended to be higher than those in the general population. However, the trend between the size of XP and serum cholesterol level was unclear. Therefore, if a patient with XP visits the hospital for surgery, it is recommended to

check the lipid profile to confirm underlying dyslipidemia regardless of the size.
