**Purpose:** This study aimed to examine the preliminary effect, feasibility, and acceptability of a lifestyle intervention program using a mobile application (app) versus the effect of a program using a booklet for adults with metabolic syndrome (MetS).

**Patients and Methods:** This trial was conducted in two community centers of Hong Kong. Participants were included if they were adults with MetS, aged over 50, and able to use a smartphone. Eligible subjects were randomly assigned to either the app group or booklet group. Those in the booklet group received a health talk and a booklet, whereas those in the app group received a health talk and a MetS app to support their exercise maintenance and health records for 3 months. Both groups received similar educational content related to healthcare for MetS clients. Data were collected at baseline (T1) and at 1- (T2) and 3-month (T3) intervals. Outcomes were body weight (primary outcome), total amount of exercise, blood pressure, and lipid concentrations. Data were analyzed using the generalized estimating equation models. Feasibility and acceptability were assessed in process evaluation.

**Results:** Ninety-eight individuals were screened for eligibility and 77 were randomized into the app group (n = 38) or booklet group (n = 39). The attrition rate at T3 was 11.690%. The app group showed a significant reduction in body weight ( $\beta = -1.069$ ,  $p = 0.012$ ) and body mass index ( $\beta = -0.371$ ,  $p = 0.026$ ), a greater amount of exercise ( $\beta = 8.454$ ,  $p = 0.032$ ), and improved exercise self-efficacy ( $\beta = 10.62$ ,  $p = 0.001$ ) within 3 months. There were no significant differences between groups for other outcomes. The participants appreciated the proposed intervention of the programme.

**Conclusion:** The MetS app may be incorporated in the health promotion programme to support exercise maintenance and a healthy lifestyle in the community.

**Keywords:** exercise, body weight, metabolic syndrome, intervention, programme, mobile application

## Introduction

Metabolic syndrome (MetS) exists in those who have a cluster of the major heart attack risk factors: diabetes and prediabetes, abdominal obesity, high cholesterol concentrations, and high blood pressure.<sup>1</sup> According to the new International Diabetes Federation (IDF) definition, a person with MetS has central obesity (defined as a certain waist circumference, which has ethnicity-specific values) and has any two of the following factors, or is receiving treatment for these:

elevated triglyceride concentrations, reduced HDL cholesterol concentrations, high blood pressure or previously diagnosed hypertension, or elevated plasma glucose concentrations or previously diagnosed type 2 diabetes.<sup>1</sup> MetS is becoming increasingly prevalent, with a prevalence of 29% to 40% in Western countries<sup>2,3</sup> and approximately 25% in China,<sup>4</sup> with an increasing prevalence in young-old adults.<sup>5</sup> MetS further deteriorates the condition of diabetes and prediabetes, cardiovascular disease, and stroke, if not well treated.<sup>1,5,6</sup>

Lifestyle modifications, such as increasing physical activity, making healthier dietary choices, and giving up smoking, have been recommended as the primary interventions for MetS.<sup>1,6,7</sup> Previous studies have reported various modalities of lifestyle intervention for MetS management, including educational programs comprising a range of educational sessions, on-site exercise supervision, and home-based lifestyle interventions that include a booklet and follow-up advice over the telephone.<sup>8–12</sup> However, these programs have been challenging to deliver in a scalable manner to meet the large demand of the MetS population. Little is known about whether the effects of these programs on exercise behavior and other outcomes can be improved by incorporating e-health technology.

E-health technology refers to the use of information and communication technologies to improve health care.<sup>13</sup> During the past decade, e-health technology using mobile applications (apps) has proved to be an effective mode of delivery for educational interventions.<sup>13–21</sup> Recent evidence has shown the effectiveness of smartphone apps at increasing physical activity in the short term (eg, up to 3 months). However, most e-health tools are web-based platforms or the apps are designed for the general public and not specifically for MetS clients. Moreover, the lack of continuous self-monitoring or individual feedback on outcomes seldom results in behavioral changes.<sup>16,20–24</sup> Hence, a highly interactive e-health mobile app (MetS app) was developed in this study. An effective MetS app should be relevant, feature personalized plans and goal setting, and address specific characteristics that suit clients with MetS (eg, should be self-managed, flexible, and interactive). Although recent studies have proposed the use of mobile apps in wellness-maintenance programs globally and locally<sup>16,19,23,24</sup> more advanced apps should be designed, applied, and evaluated for patients with specific health problems, such as MetS.

Considering the success of a previously reported home-based lifestyle-intervention program (LIP),<sup>12</sup> the advantages of e-health programs,<sup>13–21</sup> and the growing number

of young-old (aged 50 or above) adults with MetS,<sup>2–5</sup> we aimed to develop an e-health app and integrate it into a lifestyle-intervention program. The aims of this study were to examine the preliminary effect of an LIP using a mobile app for young-old adults with MetS versus the effects of an LIP using a booklet. Feasibility and acceptability of the intervention were further assessed in process evaluation. The specific objectives were to examine the effects of these programs on

1. body weight (primary outcome),
2. exercise: total exercise time per week, total amount of exercise,
3. exercise self-efficacy, and
4. MetS profiles (waist circumference, blood pressure, LDL cholesterol [LDL-C] concentrations, HDL cholesterol [HDL-C] concentrations, and triglyceride and blood glucose concentrations).
5. Feasibility and acceptability of the intervention: by examination of recruitment rate, attrition rate and feedback by participants in process evaluation.

We hypothesized that clients receiving an LIP with a tailor-made app (app group) would perform better than those in the control group receiving an LIP with a booklet, in terms of their body weight reduction. The app group would have better engagement in exercise and exercise self-efficacy, leading to improved control of their MetS risk factor profile (waist circumference, blood pressure, LDL-C and HDL-C concentrations, triglyceride concentrations, and glycemic control) within 3 months.

## Materials and Methods

### Design

The study used a prospective pilot randomized controlled trial (RCT) design, with randomization to either the intervention (the app group) or control group (the booklet group). This design was guided by the Consolidated Standards of Reporting Trials checklist.<sup>25</sup> The study was conducted from April 2018 to March 2019.

### Study Setting, Subjects, and Sample Size

The study was conducted in two community centers of Hong Kong. The community centres that regularly hold various health seminars and activities for members living nearby were used for subject recruitment. Clients voluntarily registered for our project after reading the promotional

poster. By specific appointment, subject recruitment and follow-up visits were held in the community centers or the university research center.

### Inclusion Criteria

Individuals who satisfied the following inclusion criteria were invited to participate in the RCT. Individuals were included if they were

1. ethnic Chinese;
2. owned a smartphone;
3. aged 50 or above; and
4. had MetS,<sup>1</sup> as defined by central obesity (waist circumference: male >90 cm, female >80 cm) and two of the following:
  - triglyceride concentrations  $\geq 150$  mg/dL (1.7 mmol/L), or treatment for this lipid abnormality,
  - HDL cholesterol <40 mg/dL (1.03 mmol/L) in males and <50 mg/dL (1.29 mmol/L) in females, or treatment for this lipid abnormality,
  - systolic blood pressure  $\geq 130$  or diastolic blood pressure  $\geq 85$  mmHg, or treatment of previously diagnosed hypertension, or
  - fasting plasma glucose  $\geq 100$  mg/dL (5.6 mmol/L) or previously diagnosed type 2 diabetes.

### Exclusion Criteria

Individuals with physical health problems; mental, visual, or cognitive impairments that compromised their use of a smartphone; or contraindications to walking or performing exercise were excluded.

### Sample Size

For a pilot study, Hertzog<sup>26</sup> suggested that at least 30 participants should be recruited per group. Eventually, we recruited 38 participants in the intervention group and 39 participants in the control group after taking into consideration an 18% attrition rate at 3 months of follow-up, as reported by Wang et al.<sup>12</sup>

### Randomization and Masking

Eligible participants were randomly allocated to either the app group or the booklet group. The allocation sequence was computer-generated by a statistician, and blinded to the investigators. Participants were randomized at a ratio of 1:1. A small card indicating the group assignment was placed in a sealed opaque envelope and a research assistant (RA) opened the envelope after a participant had completed

the baseline questionnaire. The outcome assessor, who was the nurse who gave the talks, was blinded to the group assignment. In addition, different follow-up dates were assigned to the two groups to avoid subject contamination.

## Intervention

### Standard Care

All participants of both groups received a 30-min educational session related to MetS, which was conducted by a nurse. The health educational session comprised a group of 8–12 participants and was held in a community center. The LIP educational session was conducted by a nurse and the content (educational session and booklet) was similar to the content used by Wang et al, except for a minor modification on dietary suggestions to suit the Hong Kong culture.<sup>12</sup> The educational content covered the knowledge related to metabolic syndrome, risk factors and its medical care, the importance of lifestyle modification such as exercise, proper diet, quit smoking and stress management. The content of the booklet was further examined by a panel of experts in Hong Kong, comprising a senior nurse, a dietitian, two nursing professors, and a MetS patient. All participants were advised to perform a brisk walking exercise or their usual exercise regimen for at least 30 minutes per day for 5 days per week, as recommended by the World Health Organization (WHO). Regular brisk walking is reported to be a safe exercise that can improve cardiovascular function and muscle strength; improve balance, blood circulation, and mood; and maintain physical and psychological well-being.<sup>27,28</sup>

### The Booklet Group

The booklet group received a health talk plus a booklet that provided an overview of MetS and its risk factors and advice on lifestyle management, a healthy diet for MetS patients, regular exercise, stress management, medication, and self-monitoring of health.

### App Group and Theoretical Framework of the App Design

The app group received a health talk and an instalment of the MetS app. The MetS app aimed to support the initiation and maintenance of behavioral changes, such as self-observation and monitoring of waist circumference and body weight, goal setting, recording and providing feedback on the amount and pattern of exercise. The design of the MetS app was based on the health belief model.<sup>29–31</sup> In this study, the program, together with the support of the MetS app, attempted to guide the

participant to achieve the above aims. In line with this construct of perceived susceptibility, severity, benefits, and barriers, the MetS app and booklet provided facts on MetS and its risk factors and the consequences of insufficient physical exercise and poor dietary control, which may lead to the progression of MetS and related complications. In addition, the benefits and positive outcomes of regular exercise were described. The MetS app was installed on a smartphone to provide health information for MetS patients, and also provided an option to support personal health and exercise self-monitoring and management strategies.

In summary, both groups received same educational content by nurse, supplemented by either booklet or app knowledge platform. However, the app provided features to further motivate and support client's individual exercise maintenance (exercise goal setting and input of exercise type and time) and self-monitoring of health record such as input and retrieve the record of body weight, blood pressure, optional blood glucose and lipid level.

### Procedure and Data Collection

Promotional posters were posted in two community centers and on the university notice boards. The health talks were conducted by a nurse as scheduled in the community centers. After the talks, potential study participants were further screened, and approached by a research assistant (RA) and invited to join the study. At the scheduled appointment, a trained RA to further confirm the individual's eligibility performed a health assessment (waist circumference, fasting glucose and lipid concentrations). Eligible participants then signed a written consent form after receiving an explanation of the project. Baseline data (T1) were collected and each eligible participant was randomly assigned to either the app group or the booklet group, after which they received the appropriate intervention according to the protocol. In follow-up appointments at T2 and T3, another RA who was blinded to the group assignment re-collected the data. The blood lipid concentration, LDL-C concentration, and HDL-C concentration data were collected at baseline, T1, and T3 only. The study flow is shown in [Figure 1](#).

### Ethical Considerations

This trial was conducted in accordance with the Declaration of Helsinki. Ethical approval was obtained from Human Subjects Ethics Sub-committee, Hong Kong Polytechnic University. All participants were informed about the purpose and procedure of the study before signing a consent form.

Participants could voluntarily join or withdraw at any time without adverse effects. Confidentiality and anonymity were assured during the study. App safety and data security were closely monitored, according to the university's guidelines for web and app safety.

### Measures

A structured questionnaire was developed to collect demographic data (age, sex, marital status, education, employment), clinical data (history of hypertension, diabetes, dyslipidemia, and smoking), and outcomes. Data were collected at T1, T2, and T3.

### Primary Outcome

The primary outcome, body weight, was measured and recorded by the research assistant at T1, T2, and T3 at a community center or university research centre using the same weight scale for each measurement.

### Secondary Outcomes

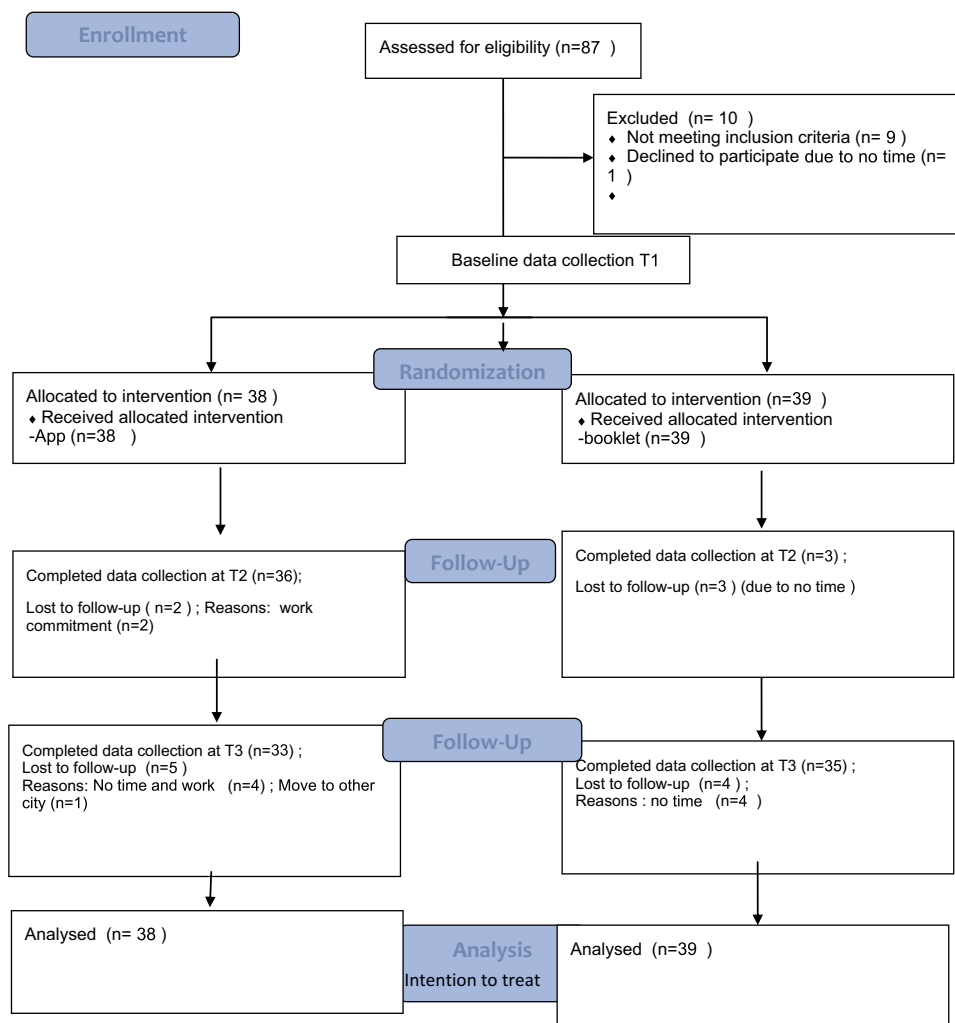

Secondary outcomes were measured at T1, T2, and T3. The total amount of physical exercise was quantified using a modified version of the Godin-Shephard leisure-time physical activity (GSLTPA) questionnaire.<sup>32,33</sup> The participants were instructed to indicate the amount of exercise they performed and to rank the exercises in order of difficulty (strenuous, moderate, or mild). The total score was then calculated. This approach has been widely used in empirical studies and has been shown to exhibit good psychometric properties.<sup>32,33</sup> Total exercise time per week was also recorded.

### Chinese Version of the Self-Efficacy for Exercise Scale

The Chinese version of the self-efficacy for exercise (SEE-C) scale consists of nine items, and responses are made on a scale of 0–10. The sum of the responses to all nine items yields the final composite score, which ranges from 0 to 90. The SEE-C has been shown to be reliable, with good psychometric properties for older Chinese adults in Hong Kong, as indicated by a Cronbach's alpha coefficient of 0.75.<sup>34</sup>

### Demographic, Clinical, and Metabolic Syndrome Risk Factor Data

Demographic data, including age, sex, occupation, educational level, and medical history, including health and drug-use history, were collected by a RA. Blood lipid data, including LDL-C, HDL-C, and triglyceride concentrations were tested by Cobas 101 Lipid testing machine (manufacturer: Roche Diagnostics); blood sugar concentrations; and all other parameters, including waist

**Figure 1** Study flow chart.

circumference and systolic and diastolic blood pressure, were collected by a RA at T1 and T3.

### Process Evaluation of Feasibility and Acceptability

To assess the implementation and acceptability of the program using the app or booklet, three open-ended questions were asked at the T3 follow-up appointment. These questions were related to satisfaction with the program, perceived acceptability of the intervention (booklet or app), and suggestions for improvement of the MetS app or the LIP booklet. The feasibility of the program was assessed by examining the recruitment rate and the attrition rate.

### Data Analysis

Data were entered and analyzed using SPSS 25.0 (IBM, Armonk, NY, USA). Baseline characteristics and blood

lipid data were compared between the two groups using a chi-square or Fisher's exact test for categorical variables, and a Student *t*-test or Mann-Whitney test for continuous variables. To compare the changes in the mean values of continuous outcome variables (waist circumference, body weight, total amount of physical exercise, and exercise self-efficacy) between the two groups, the intention-to-treat principle and generalized estimating equation (GEE) models. Generalized estimating equations (GEE) models were employed to assess differential change of the outcomes across three time points between the two groups with adjustment for potential confounding factors. The interaction effect (main effect) of the time point dummy variables and group were included in the GEE models to assess the differential change of the outcomes at each time point relative to the baseline between the two groups. GEE model can account for intra-correlated repeated measures

data and be able to fit various types of data with the use of appropriate link-function. The GEE model is chosen over the linear mixed effects model because the GEE uses sandwich estimator, which produce consistent estimates even if the correlation structure is misspecified, thus is particularly important for pilot study in which the information of the correlation structure is usually lacking. In addition, the GEE model can accommodate missing data caused by dropouts, provided that data are missing at random which is particularly suitable for ITT analysis, without the need for imputation of missing data.<sup>35</sup> Between-group Cohen's *d* were calculated to estimate the effect sizes of the app as compared to the booklet on all the outcome measures separately.<sup>36</sup> All statistical tests were two-sided and a *p*-value <0.05 was considered an indicator of statistical significance.

In process evaluation, all participants are encouraged to provide written feedback at the end of survey at T3 follow-up. The qualitative data were subject to content analysis to identify supplementary information.<sup>37</sup> To enhance the credibility of the qualitative data analysis, two researchers who are familiar with qualitative analysis adopted content analysis by identified significant statements, phrases, sentences and commonalities among the qualitative data after examining the written feedback line by line carefully, repeatedly and independently. Any discrepancies in the major categories were discussed and resolved in a meeting. The qualitative data was used to supplement and explain the findings of pilot RCT.

## Results

Data were collected from April 2018 to March 2019 in Hong Kong. Eighty-seven people were assessed for eligibility. Nine people were excluded as they did not meet the eligibility criteria for MetS after a physical assessment and one declined to participate in the study after its purpose was explained. Seventy-seven participants (38 experimental and 39 control participants) completed the study. Mean age was 57.42 (SD 6.43) and 60.45 (SD 7.49) for the App group and the control group. App group had 52.6% (*n*=20) male participants while the control group had only 35.9% (*n*=14) male participants. Attrition rates of 5.3% (*n* = 2) and 7.7% (*n* = 3) were found at T2, whereas attrition rates of 13.16% (*n* = 5) and 10.26% (*n* = 4) were found at T3 for the app and booklet groups, respectively. The total attrition rate for all participants was 11.69% at T3. No significant difference was found in demographic data between those who dropped out and those who completed the

study. Moreover, no significant differences were found in baseline demographic or outcome data between groups (Tables 1 and 2). The mean age of the participants was 58.95 years (standard deviation [SD], 7.1 years) and 44.2% (*n* = 34) of participants were male. Most participants were obese, with a mean body mass index (BMI) of 27.02 (SD, 4.21) and a mean waist circumference of approximately 96 cm (SD, 10.35 cm). Their mean systolic blood pressure was 133.17 mmHg (SD, 16.45 mmHg) and their mean diastolic blood pressure was 83.6 mmHg (SD, 14.73 mmHg). Most participants had completed secondary education or higher (84.4%, *n* = 65), were married (71.43%, *n* = 55), were working full-time or part-time (53.25%, *n* = 41), and were not currently smoking regularly (98.7%, *n*=76). The majority (80.5%, *n*=62) of participants had an exercise habit, but their mean exercise time was approximately 128 min (SD, 96 min), which was less than the exercise time recommended by the WHO (150 min per week). Their exercise self-efficacy score was below average, at 37.14 (SD, 14.65). No significant difference was found between the two groups with respect to demographic or clinical characteristics (Table 2).

Table 3 summarizes the mean, SD of outcomes and effect size and Table 4 summarizes GEE results of outcomes (body weight, BMI, waist circumference, blood pressure, lipid and fasting blood glucose concentrations, total exercise time, GSLTPA [exercise amount], and exercise self-efficacy [SEE]) across three time points between the two groups. Compared to the booklet, the app has produced medium effect sizes on weight, GSLTPA score and SEE, small effect sizes on BMI, waist circumference, systolic blood pressure and fasting blood glucose and very small effect on the remaining outcomes. At T3 (3 months), the app group showed a significant reduction in body weight compared to the booklet group ( $\beta = -1.069$ , *p* = 0.012). BMI was also significantly different between groups with better performance by app group ( $\beta = -0.371$ , *p* = 0.026).

The app group showed a significant improvement in total exercise time compared with the booklet group at T2 (1 month;  $\beta = 54.476$ , *p* = 0.003), but not at T3 (3 months). In addition, the app group showed a significant improvement in the total amount of exercise (GSLTPA) at T2 ( $\beta = 5.93$ , *p* = 0.029) and T3 ( $\beta = 8.45$ , *p* = 0.038). A significant greater increase in exercise self-efficacy was also seen in the app group at T2 ( $\beta = 7.919$ , *p* = 0.002) and T3 ( $\beta = 10.62$ , *p* = 0.001) compared to booklet group. However, there was no significant interactive effect seen for the other outcomes (blood pressure, lipid and fasting glucose concentrations) at T3.

**Table I** Demographic and Clinical Characteristics of Participants

Participants' Characteristics	All (N=77) N (%)	App Group (N=38) N (%)	Booklet Group (N=39) N (%)	p-value
Age, mean (SD)	58.95 (7.10)	57.42 (6.43)	60.45 (7.49)	0.061

**Table 2** Baseline Outcome Measures for Participants

Baseline Measures	All (N=77) N (%)	App Group (N=38) N (%)	Booklet Group (N=39) N (%)	p-value
	Mean (SD)	Mean (SD)	Mean (SD)	
Total exercise time per week Mean (SD)	127.99 (96.11)	137.5 (100.21)	118.72 (92.3)	0.395
Godin weekly leisure time activity score (GSLTPA) Mean (SD)	16.45 (11.34)	16.13 (10.68)	16.76 (12.08)	0.811
Exercise self-efficacy	37.14 (14.65)	34.61 (13.26)	39.61 (15.67)	0.134

## Process Evaluation

We assessed the feasibility of the program by examining the recruitment rate, which was 88.5%, and the total attrition rate, which was 11.69% (n = 9) at T3. Acceptability was assessed by a qualitative analysis of the perceptions of the participants. Most participants (81.58% n=31) in app group and 84.62% (n=33) of the booklet group appreciated the intervention program. The app group found that the app was useful for their exercise maintenance and that the information platform was particularly useful for their dietary choices and lifestyle modifications, such as increasing their amount of exercise. Suggested ways to further improve the app for exercise maintenance included adding a step counter (n=5) and more frequent reminder features (n=2) to the app. Overall, these findings indicated that the proposed intervention was feasible and appreciated by the participants.

## Discussion

The overall aim of this study was to examine the preliminary effect of a home-based interactive e-health educational intervention program for young-old clients with MetS, using either an app or a booklet to support their lifestyle modifications. There was no significant difference in clinical baseline demographic and outcome characteristics between the intervention and control groups. However, the total exercise time and exercise intensity of the participants at baseline were below the standard recommended by the WHO.<sup>27</sup> A significant interaction effect was observed for the primary outcome, body weight, and for BMI at T2 (3 months). These results indicated that the app effectively promoted regular aerobic physical exercise, such as brisk walking, leading to weight reduction within 3 months.

Two systematic reviews have highlighted that a successful structured e-health program should be specifically tailored to the target group and have features that support self-monitoring, feedback, the use of theory, interactivity, and goal setting to change behavior.<sup>16,38,39</sup> Given

that the same information on MetS was provided to the booklet group and to the app group, the members' area and interactive platform and other features of the MetS app may have further facilitated the self-monitoring of individual health and the recording of exercise, body weight, and waist circumference, thereby enhancing the participants' self-efficacy for adequate dietary control, exercise initiation, self-monitoring, and maintenance, leading to a greater amount of exercise and body weight reduction.<sup>29-31</sup> In addition, the alert and reminder functions of the app encouraged the participants to maintain their exercise habits.<sup>22-24</sup> Further, the results showed that the total amount of physical exercise, as measured by the GSLTPA score, significantly increased over the 3-month study period, indicating that the app was effective at promoting more moderate-intensity exercise to be performed. The intervention group also had significantly greater exercise self-efficacy than the control group over the 3-month study period.

Previous studies have consistently shown a positive effect of increased physical activity on body weight control and lipid profile over a period of 3 or more months.<sup>13,22,23,39,40</sup> The success of other programs<sup>13,16,22,23,40</sup> may be due to their labor-intensive components, such as individual counselling for dietary and exercise advice or a supervised exercise program. However, our study relied solely on the app support, leading to an increase in the amount of physical exercise and weight reduction over the 3-month study period. In this study, our intervention likely elicited short- to medium-term positive effects on physical exercise up to 3 months. Consistent with the preliminary RCT data, our qualitative findings of the process evaluation showed that the app was mostly accepted by the participants for support of their exercise maintenance. Our MetS App could be incorporated in the programme and promoted to the population on a larger scale to reduce MetS risks with limited human resource.

Lipid concentrations and blood pressure levels did not significantly differ between intervention groups, although

**Notes:** Time points (month 1, and month 3, with month 0 as reference), time points and groups interaction terms (group\*month 1, and group\*month 3,) were showed for the GEE models. Variables adjusted in the GEE models: education. All statistical tests were two-sided and a p-value <0.05 was considered statistically significant. Significant \*p<0.05, \*\*p<0.001.

the triglyceride concentrations and systolic blood pressure were lower in the app group than the booklet group. The findings were consistent with previous similar studies in China that participants in the intervention group (with more health educational support) demonstrated continuous improvements in Blood pressure control, fasting blood glucose and blood lipid level, but no significant interaction effects were detected.<sup>12</sup> This non-significant result may be attributed to the small sample size or short-term effects due to the limitations of the pilot study design. More studies might be required to confirm these outcomes.

This study has several limitations. First, the sample size was small and only two community centers were used for data collection, which may affect the generalizability of these results. Second, the data relied on participants' self-input of their exercise record and some participants may have forgotten to input their data. An objective tool for measuring exercise may be used in future studies, if funding allows. There are currently many activity-tracking devices on the market that can automatically record exercise and these could be used for such measurements. Furthermore, we made multiple

comparisons in the hypothesis testing regarding the effectiveness of the app on the outcome variables, which have inflated the overall type 1 error, and large-scale main RCTs are needed to confirm the results observed in this pilot study.

Future research should involve a large-scale multi-center study. A sustainable, longer-term effect (6 months or longer) or a more intense form of e-health intervention with a stronger dose to engage the clients' exercise sustainability might be explored further in the future.

## Conclusion

The MetS app, together with a lifestyle intervention programme, is a safe and feasible means of providing support to patients with MetS, to improve their exercise maintenance and help them with weight reduction. The MetS app developed in this study may be incorporated in the programme to support exercise maintenance and promote a healthy lifestyle in the community.

## Data Sharing Statement

The authors do not intend to share individual deidentified participant data.

## Acknowledgments

Sincere thanks to the Start-up Fund, the Hong Kong Polytechnic University for the groundwork and Health and Medical Research Fund, Food and Health Bureau of Hong Kong SAR to support our research. Special thanks to the clients who participate in our project.

## Disclosure

The authors report no conflicts of interest in this study.

### Clinical Interventions in Aging

Dovepress

#### **Publish your work in this journal**

Clinical Interventions in Aging is an international, peer-reviewed journal focusing on evidence-based reports on the value or lack thereof of treatments intended to prevent or delay the onset of maladaptive correlates of aging in human beings. This journal is indexed on PubMed Central, MedLine, CAS, Scopus and the Elsevier

Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/clinical-interventions-in-aging-journal>
