Supporting Information

**ABSTRACT:** Nanopores hold great potential for the analysis of complex biological molecules at the single-entity level. One particularly interesting macromolecular machine is the ribosome, responsible for translating mRNAs into proteins. In this study, we use a solid-state nanopore to fingerprint 80S ribosomes and polysomes from a human neuronal cell line and *Drosophila melanogaster* cultured cells and ovaries. Specifically, we show that the peak amplitude and dwell time characteristics of 80S ribosomes are distinct from polysomes and can be used to discriminate ribosomes from polysomes in mixed samples. Moreover, we are able to distinguish large polysomes, containing more than seven ribosomes, from those containing two to three ribosomes, and demonstrate a correlation between polysome size and peak amplitude. This study highlights the application of solid-state nanopores as a rapid analytical tool for the detection and characterization of ribosomal complexes.

**KEYWORDS:** nanopore, nanopipette, ribosome, single-molecule, polysome, translation

The analysis of individual biomolecular entities with nanopores is quickly emerging as a powerful bioanalytical tool. The technique is based on the principle of resistive pulse sensing,<sup>1,2</sup> wherein the temporary disruption in the measured ion current resulting from the passage of biomolecules through a nanopore is employed to study the size and conformation of the biomolecule. Over the years, nanopore sensing has been applied for numerous biomolecular analyses, including DNA translocation studies, protein detection, and nanopore-based nucleic acid sequencing.<sup>3–8</sup>

The single-molecule sensitivity of the technique has also gained increasing attention in the field of RNA biology,<sup>9</sup> and, in particular, biological nanopores have been widely used as RNA sequencing tools for molecular and clinical studies.<sup>10–12</sup> Besides sequencing, nanopores with their ability to distinguish small differences in charge and size of the translocating molecules are also excellent detection systems for studying the structure and conformation of RNA molecules. Accordingly, nanopores have been used for exploring RNA translocation dynamics,<sup>13</sup> tRNA translocation kinetics,<sup>14</sup> and to investigate the folding of RNA pseudoknot structures.<sup>15</sup> Nanopores have also been previously used to detect bacterial 50S ribosomal subunits and control their translocation,<sup>16</sup> and recently Rahman et al. reported the programmable delivery of 70S ribosomes with a nanopore integrated in an optofluidic chip.<sup>17</sup>

Despite these achievements, detection and analysis of individual ribosomes via nanopores has not yet been accomplished. Ribosomes are macromolecular machines comprising RNAs and proteins that coordinate mRNA-guided peptide synthesis, a process known as translation. Eukaryotic ribosomes are composed of two subunits, the small 40S and the large 60S, which come together to form the 80S ribosomal

complex during initiation of translation.<sup>18,19</sup> 40S subunits bind at the 5' end and scan through the mRNA sequence to find the start codon. Only then can the 60S bind to form the 80S, which is capable of synthesizing protein. Each peptide synthesis event requires only one ribosome (monosome); however, high levels of translation demand that multiple ribosomes bind an mRNA and synthesize peptides simultaneously. These multiribosome complexes are known as polyribosomes or polysomes<sup>20–22</sup> (Figure 1). Monosomes can represent efficient translation events but also spurious mRNA binding without generating a peptide, whereas the binding of multiple ribosomes to an mRNA is highly indicative of an active translation event.<sup>21,23</sup> Therefore, isolation and characterization of polysomes is important for gene expression and translational control studies,<sup>24–27</sup> specifically to investigate the levels of polysomes and monosomes, and their dynamics.<sup>23,28,29</sup>

In that regard, polysome profiling is a widely used approach to assess the global translational status of cells and tissues by separating large polysomes from small polysomes, single ribosomes, and smaller RNA–protein complexes.<sup>24,30</sup> Typically, this separation is achieved via sucrose density gradient ultracentrifugation, which involves fractionation of sucrose gradients to isolate mRNAs with respect to the number of bound ribosomes.<sup>20,31</sup> Other techniques used to achieve this

(b) Illustration of the nanopipette measurement setup and representative ion current signatures of 80S ribosomes and polysomes upon translocation.

include affinity purification and ultra-high-pressure liquid chromatography.<sup>32</sup> Although sucrose gradient ultracentrifugation is a prevalent method for polysome isolation and analysis, it requires sufficiently large quantities for data retrieval, which can be problematic for tissues or primary cells where material is limited. Moreover, the technique involves time-consuming centrifugation, which could also lead to loss of bound proteins.<sup>30,33</sup>

Here, we propose solid-state nanopores as a quick and efficient analytical tool for the detection and analysis of ribosomes at the single-entity level. In this study, we show that the characterization of nanopore ion current peak enables the detection of individual ribosomes and polysomes from both human and *Drosophila melanogaster* cultured cell lines, as well as *D. melanogaster* ovaries. Furthermore, we demonstrate the successful fingerprinting of polysome samples, differentiating large polysomes (>7 ribosomes bound to single mRNA) from polysomes with fewer ribosomes in small sample volumes of 3–5  $\mu\text{L}$ . We believe that solid-state nanopores could become a useful tool for polysome profiling to complement data generated from mass spectrometry and cryo-EM.<sup>34–36</sup>

## RESULTS AND DISCUSSION

### Detection and Analysis of 80S Ribosomes.

We investigated whether nanopores can detect 80S ribosomes and polysomes with single-entity resolution. Nanopore translocation experiments were carried out using quartz nanopipettes of  $\sim 60$  nm pore diameter, as shown in the scanning electron microscope (SEM) image (Figure 2a) with a corresponding resistance of  $135 \pm 10$  M $\Omega$  measured in 0.1 M KCl. The nanopipettes were produced via laser pulling using two-line pulling parameters (Methods and Materials section). This method of nanopore fabrication is advantageous as it involves a straightforward bench top fabrication that produces low noise nanopores with consistent and reproducible pore sizes<sup>37</sup> as indicated in the current–voltage plots (Figure 2b). The ribosomal complexes of interest were introduced inside the nanopipette in 0.1 M KCl alongside the working electrode, and a reference electrode in contact with the electrolyte was placed in an external bath. We have also tested the addition of  $\text{Mg}^{2+}$  to the measurement buffer to stabilize the ribosomes but noticed no difference in the recorded data for a 2 min trace so we used 0.1 M KCl for all experiments presented in this work. Upon application of a positive voltage to the electrode placed inside the nanopipette, the ribosome complexes translocate from inside to the outside of the nanopipette, causing a temporary decrease in the otherwise steady the ion current trace (Figure 2c).

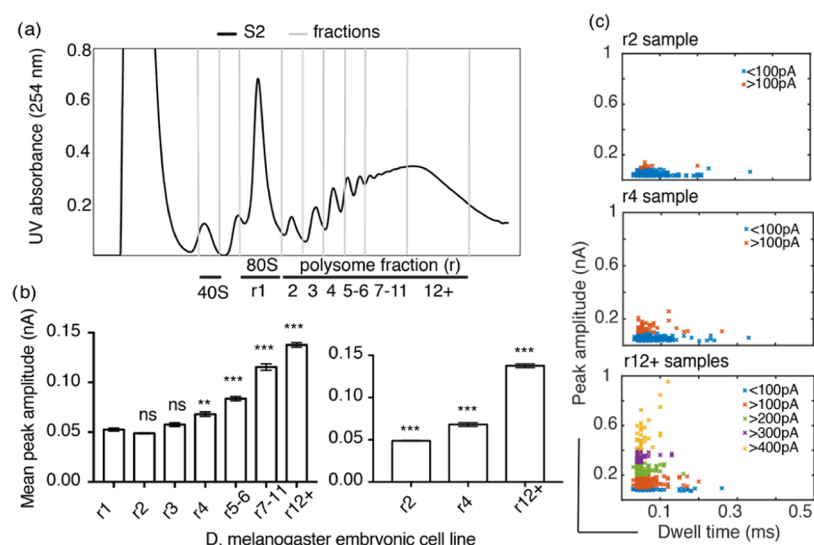

80S ribosomes extracted from an embryonically derived *D. melanogaster* cell line (S2 cells) were examined to demonstrate

**Figure 2.** (a) SEM micrograph of a nanopore at the tip of a nanopipette measuring approximately 63 nm in diameter. (b) IV characteristic of 15 nanopipettes fabricated using the same pulling parameters. (c) Representative ion current traces in the absence (top panel) and presence (bottom panel) of ribosomes, each downward spike, called events, represent an individual 80S ribosome translocating out of the nanopore. (d) Peak amplitude versus dwell time plot of 80S events of S2 cells indicating a tight cluster; the black line represents the 95% confidence ellipse.

the ability of nanopores to successfully detect individual ribosomes. These cells were chosen because it is straightforward to extract large quantities of ribosomes, and levels of polysomes are relatively high (600–1400  $\mu\text{g}/\text{mL}$  over the various gradients). Figure 2c shows a representative baseline ion current in the absence of 80S ribosomes (top trace) and an ion current trace in their presence (bottom trace), under a positive bias of 250 mV. The downward spikes or events indicate individual ribosome translocations across the nanopore. No events were detected under an applied negative voltage, indicating that the translocation of ribosomes is likely to be controlled by the electro-osmotic flow.<sup>38</sup> A typical ion current trace was recorded for 2 min.

Peak characteristic calculations for >100 such events presented a mean peak amplitude and dwell time of  $40 \pm 5$  pA and  $0.07 \pm 0.01$  ms, respectively, as shown in Figure S1. These data indicate that 80S ribosomes translocate the nanopore causing an ion current blockade larger than  $5\sigma$  from the average noise level (i.e., the false positive rate is  $\sim 1$  in 1 700 000), demonstrating the ability of solid-state nanopores to detect 80S ribosomes. The scatter plot (Figure 2d) of the events with the individual peak amplitudes versus dwell time indicates that all of the observed events cluster together as a single population within a 95% confidence ellipse.

**Figure 3.** *D. melanogaster* S2 cell polysome analysis. (a) UV (254 nm) profile across sucrose gradient with ribosomal complexes separated based on their sedimentation profile. RNP (ribonucleoproteins and RNA) remain at the top of the gradient, followed by 40S subunits, 60S, 80S, and polysomes with various numbers of ribosomes bound per mRNA. Up to 11 ribosomes per mRNA can be seen in this example; fractions were taken as indicated r1, r2, r3, r4, r5–6, r7–11, and r12+. (b) Statistical Kruskal–Wallis test for each of the polysome samples against 80S shows that there is no significant difference (ns) in the peak amplitude for r2 and r3, whereas there is a significant difference with a  $p$ -value of 0.03 (\*\*) for r4 and  $p < 0.001$  for r5–6, r7–11, and r12+ indicated by \*\*\*. Similar tests performed for r2, r4, and r12+ show that there is a significant difference between these three polysome samples, with  $p < 0.001$  indicated by \*\*\*. The error bars indicate standard error of the mean of each sample. (c) Peak amplitude plotted against dwell time for at least 100 individual events for each sample; the events are color coded to represent every 100 pA peak amplitude increase.

We also note that translocation of the small subunit of the ribosome, 40S ribosomal subunit, did not result in any detectable events (Figure S2). This observation could be explained by considering the smaller size of the 40S subunit compared to the nanopore size used in this study or slightly different relative composition in terms of RNA and protein (40S: 53% rRNA and 47% protein; 80S: 61% rRNA and 39% protein).

#### Differentiation of 80S Monosomes from Polysomes.

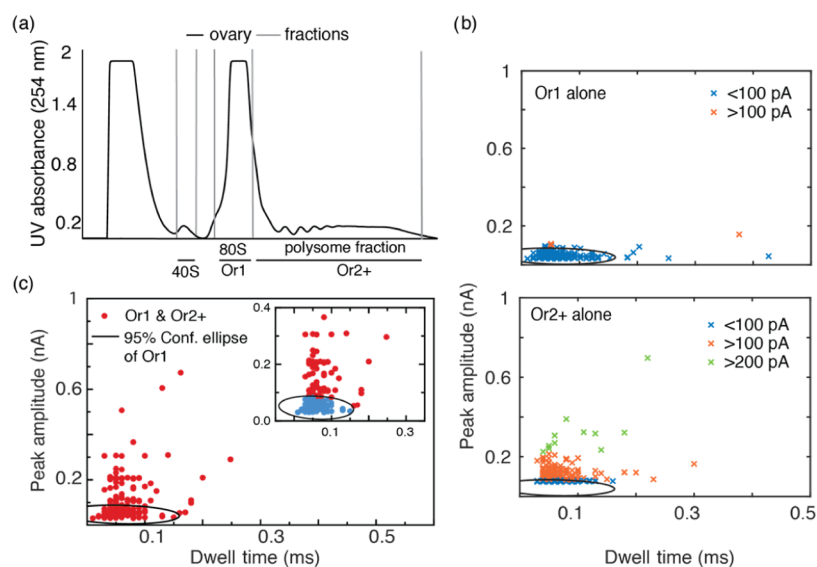

Further, we demonstrate the ability of nanopores to differentiate 80S monosomes (r1) from small and large polysomes. We selected polysomes with varying number of ribosomes bound per mRNA, obtained from *D. melanogaster* S2 cells. The polysomes were separated into fractions via sucrose gradient ultracentrifugation (Methods and Materials Section), and Figure 3a shows the separation of the polysomes into six fractions. The first three polysome fractions contain approximately two, three, and four ribosomes per mRNA referred to as r2, r3, and r4, respectively; the final three fractions are referred to as r5–6 (~5–6 ribosomes/mRNA), r7–11 (~7–11 ribosomes/mRNA), and r12+ (~>11 ribosomes/mRNA), respectively.

We analyzed the polysome samples with the nanopore setup and studied the resulting ion current events under the same conditions as before. Ion current event characterization of the different samples revealed an increasing mean peak amplitude in relation to the ribosome number per mRNA (Figure S3), with a significant difference ( $p < 0.001$ ) as shown in Figure 3b between the r4 fractions (and above) when compared to the value obtained for 80S (r1), while the difference between r1 and r2 and r3 were not statistically different. This result can be explained by the increase in the magnitude of the ion current blockade caused by an increase in the volume occupied by the sample inside the nanopore. Figure S3 shows the peak

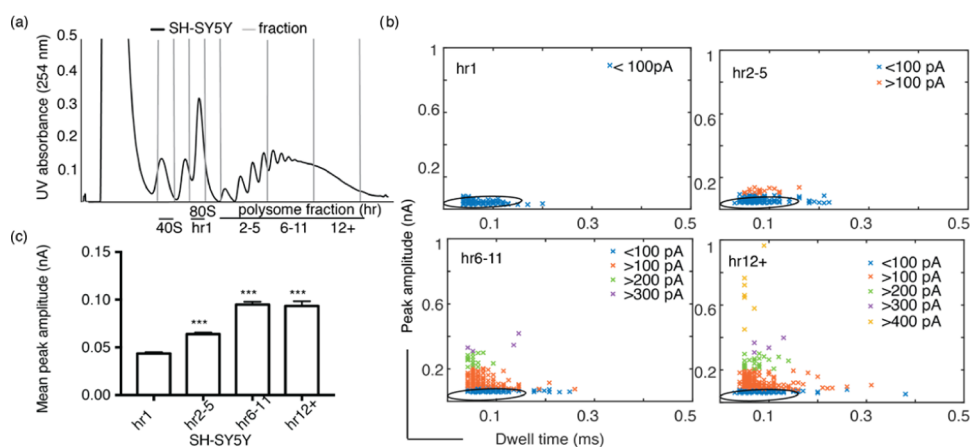

amplitude histogram for the different polysome samples. The histograms indicate the occurrence of a second cluster of higher peak amplitudes, which is in correlation with the number of ribosomes present in the polysome. For example, r2 samples, which contain mRNAs bound by approximately two ribosomes, exhibited a mean peak amplitude of  $40 \pm 10$  pA, whereas r4 bound by approximately four ribosomes and r12+ bound by approximately >11 ribosomes exhibited two mean peak amplitudes ( $r4 = 44 \pm 6$  and  $66 \pm 10$  pA,  $r12+ = 89 \pm 15$  and  $146 \pm 20$  pA). Particularly, r12+ samples exhibited very high peak amplitudes distributed over a wide range that were absent for samples with fewer ribosomes per mRNA.

In comparison, the dwell time analysis resulted in small differences between the different polysome fractions with a varied distribution of events in relation to the number of ribosomes present in the sample (Figures S3 and S5). The long dwell time events and widespread peak amplitudes could be due to multiple polysomes translocating the nanopore at the same time or long polysomes translocating the nanopore in various conformations (circularized/linear). Also, the longer dwell times and increased peak amplitudes for the r7–11 and r12+ fractions could be explained by considering the heterogeneous nature of these samples with a large number of ribosomes. Individual histogram plots of peak amplitude and dwell time for all of the polysome samples are provided in Figure S3.

From the analyzed samples, it is clear that the polysomes exhibit a higher mean peak amplitude than the 80S ribosomes. Figure 3c depicts the scatter plots for polysomes r2, r4, and r12+, demonstrating the occurrence of ion current events with a peak amplitude of >100, >200, and >300 pA, respectively. While the r2 sample has most of its ion current events within 100 pA, the r4 sample exhibits events in two groups, below and above 100 pA. This increase in peak amplitude is due to an

**Figure 4.** (a) Sucrose gradient fractions of lysates purified from *D. melanogaster* ovaries separated into 40S, 80S (Or1), and polysomes (Or2+). (b) Scatter plots for individual 80S and polysome samples obtained from *D. melanogaster* ovaries, indicating the clear difference in ion current peak characteristics between the two samples. The black circle indicates the 95% confidence ellipse fitted for 80S data and superimposed onto the polysome data. (c) Peak amplitude plotted against dwell time for 80S and polysome mixture, the zoomed in inset indicates the events that fall within the 95% confidence ellipse represented in blue.

**Figure 5.** (a) Sucrose gradient UV trace for human neuronal cell line sample (SH-SY5Y), fractionated into 40S, 80S (hr1) and polysomes hr2–5, hr6–11, and hr12+ with 2–5, 6–11, and ~11 ribosomes, respectively. (b) Scatter plots of 80S and polysomes; the graphs show a similar trend of peak amplitude increase with respect to an increase in the number of ribosomes. The hr1 data is fitted with a 95% confidence ellipse, which is then superimposed onto the polysome data. (c) Mean peak amplitude data of SH-SY5Y polysomes compared with 80S samples exhibit a significant difference of  $p < 0.001$  represented by \*\*\*. Kruskal–Wallis test was performed for this data, and the error bars indicate standard error of the mean.

increase in ribosome number (Figures S4–S6), and for r12+ samples, 80% of the events exhibit a peak amplitude of >100 pA, as shown by the differently colored clusters in Figure 3c. The noted overlap in peak amplitude between the different polysome samples could stem from consecutive fractions containing populations with overlapping number of ribosomes per mRNA; additionally, the varying RNA–protein complexes between mRNAs could also contribute to this effect. Nevertheless, the nanopores are sensitive enough to detect and differentiate 80S ribosomes from polysomes with 2–3 and >7 ribosomes per mRNA. The clear distinction between 80S ribosome samples and those containing polysomes could therefore be utilized as a quick screening technique.

Nanopore fingerprinting was also tested with lysates purified from *D. melanogaster* ovaries, wherein the concentration of polysomes (280 and 830  $\mu\text{g}/\text{mL}$ ) obtained was much lower

than that in the cell lines. Cytoplasmic lysate from ovaries was subjected to polysome profiling, and the isolated 80S ribosomes and polysomal complexes referred to as Or1 and Or2+ were then subjected to nanopore analysis (Figure 4a).

Similar nanopore translocation studies revealed that the Or1 samples exhibit ion current events with a mean peak amplitude of  $41 \pm 12$  pA and dwell time of  $0.05 \pm 0.01$  ms (Figures S7 and S8), which closely match the data obtained for S2 cell 80S samples. As expected, the polysome samples exhibited significantly different peak amplitudes of >100 pA (Figure 4b), when compared to Or1, with a distribution similar to that of the S2 cell polysome samples ( $p < 0.001$ , Figure S9). Furthermore, these results were compared with a *D. melanogaster* ovary sample containing an 80S and polysome mixture to see if we could detect proportions of 80S and polysomes in a complex sample. Figure 4c shows the

translocation events observed for the mixed fractionate, indicating two slightly overlapping clusters, one below 100 pA and the other above 100 pA, which relates well with the two individual samples. As shown in the inset of Figure 4c, the 95% confidence ellipse fitted for the individual 80S samples was used as a boundary to identify the 80S events in the mixed sample. The results highlight the potential of nanopores to accurately distinguish between single 80S ribosomes and polysomes in an unfractionated mixture. Similar studies for mixed 80S and polysome samples for S2 cells are also provided in Figure S6a,b.

Having validated the nanopore analysis of ribosome extracted from a *D. melanogaster* cell line and from an ovary sample, we then tested the ability of the nanopore platform to analyze human ribosomes, extracted from SH-SY5Y human neuronal cell line. Here, in addition to the 80S ribosomes (hr1), polysome fractions with 2–5, 6 to ~11, and ~>11 ribosomes (referred to as hr2–5, hr6–11, and hr12+) were purified (Figure 5a). The analysis of the events showed similar peak amplitude and dwell time distinctions for 80S ribosomes and polysomes as measured for *D. melanogaster* S2 cells and ovaries. Figure 5b shows the discrete differences in the peak amplitude and dwell time scatter plots for the samples (80S ribosomes and polysome fractions), with 80S exhibiting  $32 \pm 4$  pA mean peak amplitude and  $0.07 \pm 0.02$  ms mean dwell time. Again for the polysomes, as observed for S2 cells, there is an increase in peak amplitude with respect to the ribosome number. While hr2–5 samples exhibited a mean peak amplitude of  $53 \pm 12$  pA, the samples with higher ribosome numbers exhibited two groups with mean of  $56 \pm 10$  and  $91 \pm 20$  pA for hr6–11, and  $63 \pm 11$  and  $98 \pm 30$  pA for hr12+ (Figure 5c). However, all three polysome samples showed similar mean dwell times of  $0.08 \pm 0.03$ ,  $0.07 \pm 0.02$ , and  $0.07 \pm 0.02$  ms, respectively, with the large polysomes (hr6–11 and hr12+) exhibiting a wider distribution than the hr2–5 and hr1 samples (Figures S10–S13).

## CONCLUSIONS

In this study, we report the application of a solid-state nanopore for the analytical detection of ribosomes and polysomes. Characterization of these modulations allows us to detect single ribosomes and polysomes in very small-sample volumes (3–5  $\mu$ L). We demonstrate that there is a significant difference in the peak amplitude between samples containing 80S ribosomes and those containing polysomes. Specifically, we provide evidence for the correlation between the number of ribosomes in a polysome and the resulting peak amplitude. These observations are consistent across samples derived from *D. melanogaster* S2 cells, *D. melanogaster* ovaries, and SH-SY5Y human neuronal cells.

Thus, as well as being able to detect ribosomes and polysomes, these experiments reveal the ability of solid-state nanopores to differentiate large polysomes (>7 ribosomes) from polysomes with a lower ribosome count, using their peak amplitude. Furthermore, using the same technique, we generate characteristic fingerprints for single 80S ribosomes allowing us to distinguish between 80S and polysomes in mixed samples, indicating the robustness of the technique as an analytical tool.

Further extension of this study to achieve a greater separation between consecutive ribosome numbers and increased sensitivity of the nanopore to fully map the polysomes is foreseeable in the future, for example, by better

tuning the nanopore dimensions to the analyzed sample and by employing chemically functionalized nanopores.<sup>39</sup> Also, we envision that by taking advantage of the signal enhancement generated by macromolecular crowding<sup>40</sup> or by careful selection of the electrolyte,<sup>41</sup> we could better resolve the differences in dwell time and peak amplitude between the different polysome fractions. These improvements could pave the way for the use of solid-state nanopores to distinguish individual polysome fractions as an alternative or complement to sucrose density gradient ultracentrifugation but with the advantage of doing so at the single-entity level. The current study proves the potential of nanopores as a sensitive tool for the identification of ribosomes and additionally to differentiate them from polysomes in a sample. We expect that with further improvements solid-state nanopores can be a useful analytical tool, complementing cryo-EM and mass spectrometry for the structural analysis of ribosomes and ribonucleic particles.

## METHODS AND MATERIALS

**Cell Culture.** Semi-adherent S2 embryonic cells were maintained in Schneider's medium containing L-glutamine (Sigma) supplemented with 10% fetal bovine serum (FBS) (Sigma), 100 U/mL penicillin, 100  $\mu$ g/mL streptomycin, 25  $\mu$ g/mL amphotericin B (GE Healthcare), and maintained at 26 °C in nonvented, adherent flasks (Sarstedt). Human neuroblastoma SH-SY5Y cells were cultured in Dulbecco's modified Eagle's medium (DMEM 4.5 g/L glucose with L-glutamine) supplemented with 10% fetal bovine serum (FBS) and 1% (v/v) penicillin/streptomycin at 37 °C and 5% CO<sub>2</sub>.

***D. melanogaster* Husbandry.** *D. melanogaster* wild type (Dahomey) was raised on standard sugar–yeast agar (SYA). Flies were kept at 25 °C and 50% humidity with a 12:12 h light/dark cycle in 6 oz square bottom bottles (Flystuff).

**Ribosome Purification and Quantification.** All stages were performed on ice or at 4 °C wherever possible and all solutions were prechilled to 4 °C. Approximately, 300 pairs of ovaries were harvested from 3 to 6 day old females in 1 $\times$  PBS (Lonza) with 1 mM dithiothreitol (DTT) (Sigma) and 1 U/ $\mu$ L RNasin Plus (Promega) and flash-frozen in liquid nitrogen. Ovaries were disrupted using RNase-free 1.5 mL of pestles (SLS) in lysis buffer (50 mM Tris–HCl pH 8 (Sigma), 150 mM NaCl, 10 mM MgCl<sub>2</sub> (Fluka), 1% IGEPAL CA-630 (Sigma), 1 mM DTT, 100  $\mu$ g/mL cycloheximide, 2 U/ $\mu$ L Turbo DNase (Thermo Fisher), 0.2 U/ $\mu$ L RNasin Plus, 1 $\times$  ethylenediaminetetraacetic acid (EDTA)-free protease inhibitor cocktail (Roche)). SH-SY5Y cells and S2 cells were treated with 100  $\mu$ g/mL cycloheximide (Sigma) for 3 min before harvesting. Cells were pelleted at 800g for 8 min, washed in ice-cold 1 $\times$  PBS supplemented with 100  $\mu$ g/mL cycloheximide. Ovaries, SH-SY5Y cells, and S2 cells were lysed in 500  $\mu$ L of lysis buffer for  $\geq$ 30 min with occasional agitation, then centrifuged for 5 min at 17 000g to remove nuclei.

Cytoplasmic lysates were loaded onto stepwise 18–60% sucrose gradients (50 mM Tris–HCl pH 8.0, 150 mM NaCl, 10 mM MgCl<sub>2</sub>, 100  $\mu$ g/mL cycloheximide, 1 mM DTT, 1 $\times$  EDTA-free protease inhibitor cocktail) and ultracentrifuged in SW40Ti rotor (Beckman) for 3.5 h at 170 920g at 4 °C. Typically, 0.5 mL of fractions were collected using a Gradient Station (BioComp) equipped with a fraction collector (Gilson) and Econo UV monitor (BioRad). Fractions were combined according to polysome peaks, diluted to 10% sucrose, concentrated using 30 kDa column (Amicon Ultra-4 or Ultra-15), and buffer exchanged (50 mM Tris–HCl pH 8, 150 mM NaCl, 10 mM MgCl<sub>2</sub>) at 4 °C until final sucrose percentage of  $\geq$ 0.1%. The samples were quantified using Qubit Protein Assay Kit, diluted 20-fold in filter-sterilized 0.1 M KCl solution containing 10 mM MgCl<sub>2</sub>, and then frozen using liquid nitrogen in single-use aliquots.

**Nanopipette Fabrication.** The nanopipettes with ~60 nm nanopores at their tips were fabricated from quartz glass capillaries of 0.5 mm inner diameter (QF100-50-7.5, World precision Instruments, U.K.) using a Sutter instrument model P-2000 laser puller.

The pulling protocol comprised two separate lines with the parameters line 1: HEAT 775 FIL 4 VEL 30 DEL 170 PULL 120 and line 2: HEAT 900 FIL 3 VEL 20 DEL 175 PULL 180. Using these parameters, pulling highly consistent glass nanopipettes with pore sizes with variations of less than 10 nm was possible with pipettes pulled on different days. Ag/AgCl wires (0.25 mm diameter, Sigma-Aldrich, U.K.) were utilized as both the working and counter electrodes.

**Ion Current Measurements.** For the translocation experiments, nanopipettes fitted with the working electrode were filled with translocation buffer (0.1 M KCl) containing the ribosome samples at a final concentration of 20  $\mu\text{g}/\text{mL}$ . The nanopipette and a grounded reference electrode were immersed in a 0.1 M KCl solution completing the circuit. On the application of a positive potential to the working electrode, ribosomes from inside the nanopipette translocate through the nanopipette pore into the electrolyte solution, resulting in a temporary blockage of the ion current. Ion current data were acquired using an Axon instruments patch-clamp system (Molecular Devices). Measurements were recorded using the Axopatch 700b amplifier, and the data were acquired at a rate of 100 kHz and low pass filtered at 20 kHz using Pclamp 10.6 software. Initial data analysis was carried out with a custom MATLAB script (provided by Prof Joshua Edel, Imperial College London, U.K.), and further data analysis was carried out using proFit 7 (QuanSoft, Switzerland). The 95% confidence ellipse represents the area containing 95% of all single-molecule events for a particular sample.
