Background: Translation of nanomedical developments into clinical application is receiving an increasing interest. However, its use for oral squamous cell carcinoma (OSCC) diagnosis remains limited. We present an advanced nanophotonic method for oral cancer detection, based on diffusion reflection (DR) measurements of gold-nanorods bio-conjugated to anti-epidermal growth factor receptor (C-GNRs) specifically attached to OSCC cells.

Objective: To investigate in a rat model of oral carcinogenesis the targeting potential of C-GNRs to OSCC by using the DR optical method.

Materials and Methods: OSCC was induced by the carcinogen 4-nitroquinoline-N-oxide (4NQO). C-GNRs were introduced locally and systemically and DR measurements were recorded from the surface of the rat tongue following illumination with red laser beam. Rats were divided into experimental and control groups. The results were compared with the histologic diagnosis.

Results: A total of 75 Wistar-derived rats were enrolled in the study. Local application did not reveal any statistical results. DR measurements following intravenous injection of C-GNRs revealed a significant increase in light absorption in rats with OSCC compare with rats without cancer ($p < 0.02$, sensitivity 100%, specificity 89%). In addition, absorption of light increased significantly in cases of severe dysplasia and cancer (high risk) compared to rats without cancer and rats with mild dysplasia (low risk) (86% sensitivity and 89% specificity, AUC=0.79).

Conclusion: Combining nanotechnology and nanophotonics for in vivo diagnosis of OSCC serves as additional tier in the translation of advanced nanomedical developments into clinical applications. The presented method shows a promising potential of nanophotonics for oral cancer identification, and provides support for the use of C-GNRs as a selective drug delivery.

Keywords: oral cancer, squamous cell carcinoma, gold nanoparticles, anti-EGFR, nanophotonic, cancer detection

Plain Language Summary

Translation of nanomedical developments into clinical application is receiving increasing interest in recent years, with actively targeted nanoparticles being studied as a diagnostic tool and as a selective drug carriage.

We present an advanced nanophotonic method for cancer detection. The method is based on measuring the reflected light from a tissue (diffusion reflection-DR) following the introduction of gold nanoparticles (GNPs). As GNPs absorb light in the red to infra-red spectrum, illumination with red color laser beam will yield a decrease in the reflected light compared to a tissue without gold nanoparticles.

Head and neck cancers including oral cancer exhibit an increased expression of epidermal growth factor receptor (EGFR) on their cell membrane. Specific attachment of GNPs to oral cancer cells is achieved by binding the GNPs with antibodies against EGFR and once injected systemically they are attracting the oral cancer site and are easily detected by using the DR photonic method.

In the present study, we investigated in a rat model of oral carcinogenesis the targeting potential of systemically administration of GNPs to oral cancer and the detection of the cancerous lesion using the DR optical method. The results are promising, DR measurements recorded from the surface of the tongue following intravenous injection of GNPs revealed a significant increase in light absorption in rats with oral cancer compare with rats without cancer.

Combining nanotechnology and nanophotonics for in vivo diagnosis of oral cancer serves as an additional tier in the translation of advanced nanomedical developments into clinical applications. The presented method shows a promising potential of nanophotonics for oral cancer identification and provides support for the use of C-GNRs as a selective drug delivery.

Introduction

Translation of nanomedical developments into clinical application is receiving increasing interest in recent years, with actively targeted nanoparticles being studied as a diagnostic tool and as a selective drug carriage specifically to cancerous sites.¹⁻⁴ Despite the plethora of studies published in the literature, the clinical use of nanoparticle-based agents used for in vivo oral cancer diagnosis and treatment remains limited.⁵⁻⁷

Oral squamous cell carcinomas (OSCC) arising from the mucosal surface of the oral cavity are among the ten leading cancers worldwide with about 50% 5-years survival rate mainly because of late detection.^{8,9} Several adjunctive tests have been applied for early diagnosis, however, none has been recommended for routine clinical use to replace clinical oral examination.^{10,11}

Nanoparticles have been studied and applied in the field of tumor diagnosis and treatment and have attracted attention as contrast agents to enhance imaging of oral cancer,^{6,7,12-15} yet, these methods do not affect clinical practice. Due to the remarkable properties of gold nanoparticles, they are considered as a potential tool for cancer diagnosis and drug delivery applications.

Nanophotonics has emerged as an innovative way in the field of medicine mainly to detect and imaging cancer utilizing the unique light absorption properties of gold-nanorods (GNRs) in the red to infra-red spectrum.^{16,17}

GNRs bio-conjugated to anti-epidermal growth factor receptor (C-GNR) monoclonal antibodies are supposed to attach exclusively to OSCC cells expressing high concentration of EGFR, making them an ideal target for C-GNRs.¹⁸⁻²¹ We have recently described on paraffin-embedded tissue sections of OSCC incubated with C-GNRs, a significant increase in light absorption using diffusion reflection (DR) measurements following illumination with a red color laser beam.^{16,17} In vivo studies are needed to investigate the accuracy and applicability of these nanomedical methods in clinical use.

The main perspectives of the study were to investigate in a rat model of oral carcinogenesis the potential of the DR optical method to detect OSCC specifically targeted by C-GNR and to discriminate cancerous and high-risk lesions from non-cancerous low-risk lesions.

Materials and Methods

Carcinogen-Induced Squamous Cell Carcinoma in Rat Tongue

The protocol involving animals was approved by the Institutional Animal Care and Use Committee of the Tel Aviv University, and the Ministry of Health, authorization No. 01-16-107, (The procedures described are according to National Research Council (US), Guide for the Care and Use of Laboratory Animals. 8th edition. Washington (DC): National Academies Press (US); 2011). The study followed strict criteria for the use of minimum number of rats.

A rat model of oral carcinogenesis using 4-nitroquinoline-N-oxide (4NQO) administered via drinking water is a well-known model simulating the development of oral cancer in humans.²³⁻²⁵ The study group consisted of Wistar-derived male rats weighing about 200g. Rats were fed standard pellets and water ad libitum. 4NQO (Sigma-Aldrich) dissolved in dimethyl sulfoxide (Sigma-Aldrich) and then in tap water to a final concentration of 0.001%. Water was replaced once a week with a freshly prepared solution. Bottles of drinking water were shielded with aluminum foil. Animals were carefully inspected daily.

The Experimental Set-Up

GNRs sized 15X50 nm, were selected as targeted contrast agents because of the high scattering and absorption properties compared to gold nanospheres.^{26,27} Rod shape nanoparticles in the circulation have an increased tendency to migrate toward vessel walls and extravasate easily into the

tumor microenvironment.^{5,28,29} Conjugated Gold nanorods with anti-EGFR monoclonal antibody Cetuximab (C-GNR) were used to target OSCC (NanoPartz™ Canada). The extinction coefficient spectrum of the GNRs was determined using a spectrophotometer, and the resultant extinction peak was 650nm.

C-GNRs were introduced in three routes, external application to the surface of the tongue, direct submucosal injection and systemic injection via the tail vein. A C-GNR concentration of 6mg/mL was chosen to be used for the study; 50 μ L in the external application and in the submucosal injection, and 200 μ L for the intravenous administration. Following an interval of 96 hours, rats were sacrificed and sent for DR measurements. The concentration of the injected C-GNRs and the interval for the DR measurements were investigated preliminarily for the best DR results.

Table 1 depicts the various study groups. Rats were divided into normal healthy rats and rats treated with 4NQO and whether or not C-GNRs were injected. Rats treated with 4NQO were divided histologically according to severity of the dysplastic changes (mild dysplasia, moderate and severe dysplasia and invasive cancer).

The experimental setting of the systemically injected C-GNRs is presented in Figure 1. In all rats, 3–5 DR measurements were recorded for each area, in the posterior dorsum of the tongue, an area where cancer might develop, and from the anterior tongue.

After DR recording, a mid-lingual incision was made and specimens were fixed in 10% buffered formalin and embedded in paraffin. Two consecutive 5 μ m sections were cut on a glass slide. One slide was stained with Hematoxylin and Eosin (H&E) to evaluate the histologic diagnosis, and one unstained slide was submitted for hyper-spectral imaging.

Diffusion Reflection (DR) Measurements

The noninvasive optical technique was used for the DR measurements, as has been previously reported.^{30–32} Briefly, the set-up includes an excitation source, which illuminates the tissue with a laser diode with wavelengths of 650 nm, and a photodetector recording the reflected intensity (Γ) in different distances (ρ) from the light source. The spatial intensities present a clear difference between the reflectance of the regular tissue, while the intensities from the normal tissue are high and decrease rapidly toward zero intensity for tissues with GNRs. The low intensity, as well as its rapid decrease, is due to the absorption of light by the GNRs, indicating the presence of GNRs in the cancer. In our previous study,³³ we have introduced the mathematical correlation, which best fit between the optical properties of the irradiated tissue and its DR profile measured by our optical set up:

$$\ln(\rho\Gamma(\rho)) = C_1 - \mu\rho$$

while μ is the effective attenuation coefficient, given by:

$$\mu = \sqrt{3 \cdot \mu_a \mu_s'}$$

when ρ is the distance between the light source and the detection, Γ is the reflectance intensity, C_1 is a constant depends on the optical set up apertures, and μ is the effective attenuation coefficient, which depends on μ_a and μ_s' , the absorption and the reduced scattering coefficients of the irradiated sample, respectively. In order to extract μ , we are presenting the results in the logarithmic form $\ln(\rho\Gamma(\rho))$.

The reflected intensity $\Gamma(\rho)$, presenting as units of Volt per mm, was collected using a digital scope (Agilent Technologies, Mso7034a, Santa Clara, CA, USA) and data processed using the LabView program.³⁴

The resultant intensity (Γ) is plotted as the logarithm of the product between the distance and the reflectance versus the

Table 1 The Study Groups. Rats Were Divided According to the Histologic Diagnosis and Whether or Not C-GNRs Were Injected. Rats Treated with 4NQO Were Divided According to Various Dysplastic Changes (Hyperplasia, Mild Dysplasia, Moderate to Severe Dysplasia and Cancer)

Group	A	B	C	D	E	F
Rats	Healthy rats	4NQO treated	Healthy rats	4NQO treated	4NQO treated	4NQO treated
Histology	Normal mucosa	OSCC	Normal mucosa	Hyperkeratosis Mild dysplasia	Moderate To Severe dysplasia	OSCC
Injected C-GNRs	–	–	+	+	+	+

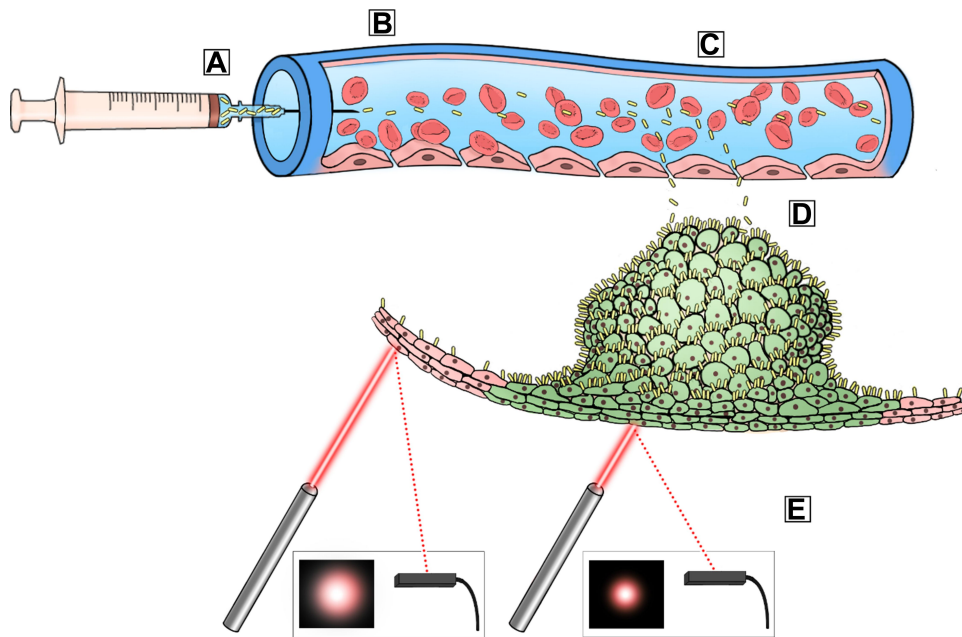

Figure 1 Experimental setup. (A) Injection of GNRs to the rat's tail vein. (B) GNRs are flowing in the rat's circulation. (C, D) At the area of the tumor there is higher penetration of the blood vessels, since the tumor over express EGFR on the cell membrane, GNRs are attached to the tumor in high concentration. (E) DR measurements are being recorded; the absorption of the red color laser beam is higher at the area of the tumor where there is high concentration of GNRs. It is also possible to see the illustration of the cell membrane with the attached GNRs (all images used in Figure 1 are original).

distance (ρ). Therefore, for tissue with high absorption of light, the graph slope is steeper. For convenience, the slope obtained from reflectance measurements is given as absolute value.

An example of how DR results are analyzed is presented in Figure 2, the reflected light is measured and the logarithm representation of the measurement according to Eq.1 is

Figure 2 Example of logarithm representation of DR measurements. The logarithmic product between the distance and the reflectance (Γ) versus the distance (ρ). DR profile of a healthy rat (group A – black triangles) has a lower absolute slope compared to a rat with cancer (group F – blue circles).

presented. The slope of a rat with cancer (group F - blue circles) is higher than the slope of a healthy rat (group C - black triangles) due to the higher concentration of C-GNRs.

Hyperspectral Microscopy

A hyperspectral imaging system (Nuance, Cri, Woburn, MA, USA) was used to demonstrate the presence of the GNRs in the tissue to validate the results of the DR measurements.

Formalin-fixed paraffin-embedded tissue sections were used. After deparaffinization, the area of interest, the area corresponding to cancer, was marked on the slide and viewed under hyperspectral microscopy. The reflectance intensities from each sample were captured and analyzed at 650nm, according to the GNRs excitation peak.

Statistical Analysis

Of the various DR measurements, we found that the lowest DR values, which correspond to the maximum absorption of light (highest DR slope values) gave the biggest Area Under ROC Curve (AUC), i.e. the best discrimination. Therefore, we present the results for the absolute values of minimum DR measurements.

We used exact Mann–Whitney (MW) and Kruskal–Wallis (KW) tests to compare DR in two or more groups.

The first analysis was to find whether the injected C-GNR accumulated in the cancerous site by analyzing the DR values between rats with cancer (group F) against control rats (group C). Then, we analyzed the discrimination ability of the DR measurements after C-GNRs injection between rats with low-risk lesions (control and mild dysplasia combined, groups C and D) with rats with high-risk lesions (moderate to severe dysplasia and OSCC combined, groups E and F). We used Cuzick non-parametric test for trend, to test if the absorption of light increases with the stage of tumor evolution. We applied ROC analysis to estimate the test in whole. The general discrimination ability was expressed using Area Under Curve

(AUC). We fixed the cut-point that reached the maximum sum of Sensitivity and Specificity in comparison between groups C and D versus groups E and F. After fixing the cut-point we compared the results by the Exact Fisher (EF) test for 2x2 tables. We also calculated the Diagnostic Odds Ratio (DOR) that is defined as

$$(\text{sensitivity}) * (\text{specificity}) / ((1 - \text{sensitivity}) * (1 - \text{specificity})).$$

OSCC developed in all rats in the posterior dorsum of the tongue, therefore, we compared the DR in the posterior and anterior parts using exact paired Mann–Whitney (Wilcoxon) test.

The whole analysis was repeated after exclusion potential outliers from measurement in a region if there were 3 measurements in the region. The results were quite similar and are not shown.

The analysis was done using STATA 16 SE software. All tests were two-sided. P-values under 0.05 were described as significant.

Results

A total of 75 rats were enrolled in the study, of these 8 rats for the surface application, 13 rats for the direct submucosal injection and 29 rats for the intravenous application. In addition, 15 rats were used to determine the concentration and the interval for the DR measurements. Ten rats expired during the study. 4NQO was administered for 16 weeks, and rats were sacrificed at two-week interval starting at week 10 until week 26. The severity of the dysplastic changes increased with time. Cancer was initially found at week 14 and the experiment terminated at week 26. Cancer developed in the posterior dorsum of the tongue in all rats (Figure 3A and B), various dysplastic changes were found throughout the mucosa of the tongue.

Figure 3 (A) Cancer in the posterior dorsum of the tongue (arrow), (B) Low-power photomicrograph showing typical well differentiated squamous cell carcinoma exhibiting deep invasion (hematoxylin and eosin stain, original magnification $\times 40$), (C) hyperspectral imaging, GNRs are shown as red dots, higher magnification of the marked area shown in B (original magnification $\times 200$, scale bar is $500\mu\text{m}$).

DR Measurements

External application yielded no results; the C-GNRs could not penetrate the keratin barrier. In the direct submucosal injection, DR measurements could not separate cancerous from non-cancerous lesions as the C-GNRs accumulated at the site of injection and did not spread in the cancer. Therefore, only the results of the systemic administration are presented (Table 2). The experimental group consisted of 9 rats with cancer (group F); and 9 rats with various dysplastic lesions (group D and E). Control rats included 6 rats without the administration of C-GNRs (group A and B), and 5 rats without cancer, but with systemically administration of C-GNRs (group C).

C-GNRs were injected systemically to all rats in groups C, D, E, and F, and DR measurements were recorded in all rats.

Summary of the data is presented in Table 2 and Figures 2 and 4. The highest absolute DR slope values were recorded in rats with cancer (group F) and in rats with moderate to severe dysplasia (group E). The lowest values were recorded in rats with hyperkeratosis and mild dysplasia, and in all of the control rats reflecting the low concentration of EGFR (see Statistics).

Figure 3C presents the hyperspectral image, C-GNRs are clearly demonstrated as red dots concentrated at the cancerous area.

Table 2 Summary of the Data. Experimental and Control Rats, Diagnosis and Absolute Minimum DR Measurements for Anterior and Posterior Dorsum of the Tongue

Rat	Group	Diagnosis	DR Measurements Posterior Dorsum	DR Measurements Anterior Dorsum
1.	A	Control with no gold	0.1773	0.24

Note: C-GNRs were injected in all experimental rats (group D, E, F) and in control rats group C.

Abbreviations: A, group A control healthy rats with no C-GNR injected; B, group B control rats with cancer with no C-GNR injected; C, group C control healthy rats with gold injected; D, group D experimental rats – hyperplasia/mild dysplasia; E, group E experimental rats – moderate/severe dysplasia; F, group F experimental rats – OSCC.

Figure 4 DR measurements of the study group. The highest absolute DR slope values were recorded in rats with cancer (group F) and in rats with moderate to severe dysplasia (group E). The lowest values were recorded in rats with hyperkeratosis and mild dysplasia and in all of the control rats reflecting the low concentration of EGFR. The oblique line represents the trend; a significant trend of the DR measurements in the posterior area correlated with the progression of the severity of the lesions (Cuzick trend test, $P = 0.018$).

Statistical Analysis

Comparison of the DR values in the posterior tongue between the three control groups A, B, and C did not reveal any statistical differences (Kruskal–Wallis $p=0.4862$). The DR values in healthy rats with injected C-GNRs (group C) did not differ from healthy rats without injected C-GNRs (group A) (exact MW $p=0.79$) and the absorption of light was even slightly less in group A than that in group C (Exact MW $p=0.25$).

DR measurements following intravenous injection of C-GNRs revealed a significant increase in light absorption in rats with cancer (group F) compared with rats in group C ($p<0.02$, sensitivity 100%, specificity 89%) (Figure 4).

A significant trend of the DR measurements in the posterior area correlated with the progression of the severity of the lesions (Cuzick trend test, $P = 0.018$) (Figure 4). ROC analysis revealed $AUC=0.79$ (95% $CI=(0.56, 1.0)$). A significant difference was found between high-risk rats (groups E, F) and low-risk rats (groups C, D); The best cut-point for discrimination was defined as 0.245 and the corresponding sensitivity was 86% and specificity 89%. $DOR=48$ (Table 3).

The differences in the DR measurements between the posterior and anterior parts were found only in the

cancerous group F (Wilcoxon $p=0.0039$). In all other groups, no differences were encountered due to the presence of dysplasia throughout the entire tongue epithelium.

Discussion

Most oral cancer cases are discovered in advance stage; therefore, secondary prevention is the key to prevention, which means detecting cancers in early enough stage that they can be treated. Several adjunctive tests have been applied for augmenting the diagnosis, such as cytological

Table 3 Statistical Analyses for Comparison Between the High and Low Risk Groups (C, D versus E, F)

Risk/Group	Number of Rats/Diffusion Reflection		Total
	DR<0.245	DR≥0.245	
Low risk (C, D)	8 88.98	1 11.11	9 100.00
High risk (E, F)	2 14.29	12 85.71	14 100.00
Total	10 43.48	13 56.52	23 100.00

testing, autofluorescence, and tissue reflectance methods, nevertheless, the potential benefit of these devices for cancer diagnosis in the oral cavity is debated.¹¹ Real-time optical diagnostic methods, such as Raman spectroscopy, elastic scattering spectroscopy, diffuse reflectance spectroscopy, narrow-band imaging, and confocal reflectance microscopy emerged to distinguish malignant from benign oral lesions,¹⁰ however, these methods are still under investigation and are yet of limited clinical use.

The present study shows the potential of the DR optical method to detect OSCC specifically targeted by systemically delivered C-GNR. OSCC was identified in all rats with cancer compared to control rats with 89% sensitivity and 100% specificity. In addition, a significant difference was found between rats with high-risk lesions (groups E, F) compared with low-risk rats (groups C, D) (sensitivity 86% specificity 89%). Discriminating low-risk lesions (hyperkeratosis and mild dysplasia) from high-risk lesions (moderate to severe dysplasia and OSCC) is of utmost importance as these lesions are prone to transform into invasive cancer.^{10,35} DR measurements taken from rats with dysplastic lesions show a significant trend; increase in the absorption of light with the increase of the dysplastic severity and dramatic increase once cancer is detected (Cuzick trend test, Prob = 0.018). These results are in accordance with our previous *in vitro* study using hyperspectral microscopy on paraffin-embedded tissues, showing an increase in the reflectance intensity with the progression of the disease, lowest in the control group and increasing as the dysplastic changes increase.¹⁷ Additional support came from the study of Ankri et al using airSEM microscopy on OSCC slides,²² showing a gradient decrease of C-GNRs concentration from the tumor to normal epithelium. Specifically targeting high concentration of C-GNRs exclusively to oral tumor cells and the DR-nanophotonic detection of these nanoparticles from the surface of the tongue makes the presented method unique for early detection of OSCC. An interesting observation is the differences between the anterior and posterior tongue, the main statistical differences were found in the carcinoma cases and not in the dysplastic cases. These results support the field cancerization theory as the entire tongue is affected by the carcinogen.

For efficient targeting and imaging, several aspects are to be considered. The nanoparticles should have the best physical design to enhance imaging, the biology of the tumor to be targeted, and the coating moieties that will confer the best specific active binding potential.^{2,6} In

addition, biocompatibility and cytotoxicity are factors to be considered.

GNRs sized 15X50 nm, were found to be highly feasible for the study because of the maximum absorption and scattering properties at the red to infrared light spectrum.^{17,22,24} Size is known to affect the distribution of the nanoparticles, the smallest GNPs revealed the most widespread distribution.^{36–38}

Tumor penetration through the vasculature is the first barrier for nanoparticles to gain access to the tumor micro-environment. The enhanced permeability and retention (EPR) effect is responsible for passive GNPs accumulation in the microenvironment.⁵ Recent study found that passive extravasation contributed only a fraction of the nanoparticle tumor accumulation, and up to 97% of nanoparticles use an active process through trans-endothelial pathways.³⁹

Active targeting, the result of specific binding to cancer cells, enhances the retention of the nanoparticles in the tumor environment.^{2,27} The use of specific ligands as binding molecules relies on the fact that several receptors are frequently overexpressed in solid tumors.⁴⁰ Head and neck cancers including oral cancer exhibit an increased EGFR expression.^{18–21} Specific binding of gold nanorods to oral cancer cells is achieved by conjugating with Cetuximab, a chimeric monoclonal mouse-human immunoglobulin G1 (IgG1) antibody. Cetuximab binds specifically to the extracellular ligand-binding domain of EGFR with a binding affinity that is two log units greater than that of EGF or TGF- α .^{41,42} The hyperspectral results demonstrate the presence of increased concentration of C-GNRs in the area related to the tumor (Figure 3).

GNPs have an excellent stability and biocompatibility, tailorable shapes and sizes, an easily functionalized surface, high drug-loading capacity, and low toxicity.⁴³ These properties considered GNPs as a potential tool for diagnosis, imaging and treatment of various cancers, including oral cancer.^{5–7,27,35,44,45} Nevertheless, despite all these benefits, biocompatibility and cytotoxicity of the GNPs is still a factor to be considered. Several assays have been used to study the toxicity of GNPs in biological systems presenting a clear size-dependence.⁴⁶ To reduce toxicity, GNPs are coated with PEG rendering the nanoparticles perfectly soluble in water and minimizes any protein adsorption.⁴³

Even though basic research studies have revealed a greater promise of nanomaterial to improve prognosis, none was translated into clinical benefits for oral cancer patients.⁷ Accurate and early detection of OSCC and high-

grade dysplastic lesions is a critical challenge. The superficial presence of OSCC and the overexpression of EGFR make these tumors ideal for the use of nanophotonic-based detection. The use of gold nanoparticles combined with nanophonics for in vivo diagnosis of OSCC suggests a promising potential for oral cancer detection. In addition, providing a significant support for the use of C-GNRs for selective drug delivery.

International Journal of Nanomedicine

Dovepress

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-nanomedicine-journal>
