ABSTRACT

Background: Acute invasive fungal rhinosinusitis (AIFRS) is aggressive morbidity affecting immunocompromised patients. Coronavirus disease 2019 (COVID-19) may allow secondary fungal disease through a propensity to cause respiratory infection by affecting the immune system leading to dysregulation and reduced numbers of T lymphocytes, CD4+T, and CD8+T cells, altering the innate immunity. The aim of this study is to evaluate the incidence of acute invasive fungal rhinosinusitis (AIFRS) in COVID-19 patients.

Methodology: Data for acute invasive rhinosinusitis was obtained from the Otorhinolaryngology departments at our tertiary hospital at the period from January 2017 to December 2020. Then the risk factors of comorbid diseases and fungal types between post-COVID-19 and non-COVID-19 groups regarding the incidence of AIFRS are compared.

Results: Consequently, the incidence of AIFRS showed a more significant difference ($P < 0.05$) in post-COVID-19 patients than in non-COVID-19 especially in immunocompromised patients, diabetic, renal, and liver dysfunction patients as well as patients with risk factors of AIFRS. The most common organisms affecting patients with AIFRS are *Rhizopus oryzae*, *Aspergillus fumigatus*, and *Absidia mucor*.

Conclusions: The incidence of AIFRS is markedly prominent in post-COVID-19 patients than in those of non-COVID-19, especially in immunocompromised, diabetic, renal, and liver dysfunction patients and patients with risk factors for rhinosinusitis.

1. Introduction

Fungal sinusitis can be categorized into non-invasive and invasive groups. While non-invasive fungal sinusitis does not exhibit the penetration of mucosa by hyphae; in invasive fungal sinusitis hyphae do invade the mucosa [1].

Acute invasive fungal sinusitis is considered the most aggressive form of sinusitis. It can be more commonly found in immunocompromised patients and notably can lead to serious morbidity and mortality. Immunosuppression in these patients can be a result of widespread sources including hematologic malignancies, diabetes mellitus, solid organ or bone marrow transplantation, chemotherapy-induced neutropenia, and advanced AIDS. Furthermore, it is as a rule with sudden critical advancement of nasal congestion, facial pain, epistaxis and

fever. Expansion into the sinus or intracranial compartments can lead to neurological impairments [2,3].

Fungal spores are copious in the nose and paranasal sinuses. These spores can lead to a pathological affection if the environment is suitable for their growth and active invasion of tissues. Normally, inhaled fungi form a part of the normal sinonasal flora, but they are significantly destroyed by the immunological system. However, in conditions such as prolonged antibiotics use, poor ventilation and moist environment as well as immunocompromised patients, these immunological pathways may be disrupted, making fungal invasion more likely to make a morbid affection of tissues [4].

Infection is often thought to arise in the nasal cavity (commonly the middle turbinate) and progress to the paranasal sinuses [5]. This

E-mail address: doctorabdulkarim7@gmail.com (A. Hasan).

suggests the involvement of multiple fungal agents, such as *Aspergillus* species (commonly in neutropenic patients), *Zygomycetes* (commonly in diabetic patients), *Rhizopus* species, *Absidia* species, *Mucor* species, and *Rhizomucor* species [1].

COVID-19, caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), is a primary acute respiratory disease which can lead to severe acute respiratory distress syndrome (ARDS), multiple organ dysfunction, and even death. Therefore, identifying risk and protective factors for COVID-19 is critical to developing efficient intervention and prevention strategies [6].

Particular pathophysiologic features of COVID-19 that may allow secondary fungal disease, a propensity to cause respiratory infection, may upgrade the risk of invasive fungal rhinosinusitis. Moreover, the immune dysregulation associated with COVID-19, with reduced numbers of T lymphocytes, CD4+T, and CD8+T cells, may alter innate immunity [7].

COVID-19 is associated with a significant incidence of secondary infections, both bacterial and fungal probably due to immune dysregulation. Additionally, the widespread use of steroids/monoclonal antibodies/broad-spectrum antibiotics as part of the armamentarium against COVID-19 may lead to the development/exacerbation of pre-existing fungal diseases [8].

Acute invasive fungal rhinosinusitis is a rare, albeit highly comorbid,

infection affecting immunosuppressed individuals. It may appear in patients with high risk of complications morbidity in the setting of COVID-19-related acute respiratory distress syndrome [9]. Therefore, the aim of this study is to evaluate the incidence of acute invasive fungal rhinosinusitis in COVID-19 patients.

2. Material and methods

2.1. Ethical considerations

The bioethical approval was obtained from Al-Azhar University, Damietta faculty of medicine for this study (IRB 00012367 / 20- 11- 002). This retrospective study was conducted for patients with AIFRS at the period from Jan 2017 to Dec 2020 at Otorhinolaryngology departments of Al-Azhar University in both Cairo and Damietta branch, Egypt.

2.2. The inclusion criteria

Patients of any age and sex. AIFRS diagnosis based on clinical, endoscopic diagnosis (Fig. 1) and positive findings for acute sinusitis on sinus computed tomography (CT) scan (Fig. 2) and MRI (Fig. 3) in addition to fungal determination by histopathological examination of

Fig. 1. A photo of an endoscopic examination with ischemic changes in the middle turbinate suggesting AIFRS.

Fig. 2. A CT picture of nose and paranasal sinuses of AIFRS with orbit invasion.

specimen of affected tissues for detection of the type of fungi. Positive PCR was confirmed from the patient's files at the isolation hospitals for COVID 19 group. Participants who did not meet inclusion criteria were excluded. Such as Patients who had acute rhinosinusitis (ARS) other than fungal type such as odontogenic rhinosinusitis and bacterial rhinosinusitis.

2.3. Sample collection

Our samples were collected each year separately (from 2017 to 2020). Each year was recorded as demographic data of the patients, onset and duration of the disease, etiology of RS, risk factors or complications. All collected data and laboratory findings were recorded and statistically analyzed then tabulated for comparison purposes.

2.4. Statistical analysis

Statistical analyses were performed using SPSS v23 statistical software (SPSS, Inc., Chicago, Illinois). Descriptive statistics (means,

standard deviations, frequencies, and correlation coefficients) were calculated for all measures. To compare the two groups, a paired *t*-test was carried out to determine *P* values using the Pearson's correlation test and a χ^2 test and a one-sample *t*-test and Wilcoxon test performed when appropriate. The level of significance calculated as $P < 0.05$ was considered statistically significant, while $P > 0.05$ was considered statistically non-significant.

3. Results

The study included 56 patients with acute invasive fungal rhinosinusitis: 30 males and 26 females. They were collected from the year 2017 to 2020. Nine patients in 2017, 8 p in 2018, 10 in 2019 and 29 patients in 2020 as shown in [Table 1](#).

Diabetes mellitus, liver and renal dysfunction, immunosuppressive drug, and leukemia were the common risk factors of AIFRS patients as shown in [Table 2](#). In comparison of these common risk factors between Post-COVID-19 and Non-COVID-19 AIFRS patients [Table 3](#) showed a statistically significant difference ($P < 0.01$).

between the two groups (P < 0.05) as shown in Table 5.

4. Discussion

Although AIFR is rare, it is the most aggressive form of fungal infection [1,10]. It is most commonly encountered in immunocompromise patients. These have two categories and each of these has commonly associated pathogens with them. The first is diabetic patients (roughly 50%), particularly if poorly controlled, and is frequently

associated with diabetic ketoacidosis. Second is the defect in immune system such as hematological malignancies and chronic renal insufficiency [4,11].

Pathology examination is the corner stone in diagnosing several challenging diseases including the fungal sinusitis, where is the microscopic examination of fungal ball on low power might be confused with the eosinophilic mucin seen in allergic rhinosinusitis, since both have a “layered” appearance, but this confusion is usually lost on high power revealing abundant fungal organisms [12–15].

Our patients were diabetics in 44.4% of post-COVID-19 AIFRS and in 28.9% of AIFRS patients with non-COVID-19. Bakhshaei et al. [1] found that the most common underlying disorder in AIFRS patients was diabetes mellitus (50%), then leukemia (44.4%). In studies of Kursun et al. [16], Mohammadi et al. [17], Kermani et al. [18], the most common underlying disorders affecting the immune system were the diabetes mellitus and, to a lesser extent, hematological malignancies and chronic renal insufficiency. This may be due to the fungal affinity for acidotic environments with high glucose concentrations [19].

The second subset of patients are those who are immunosuppressed such as those with neutropenia, HIV/AIDS, hematological malignancies and patients receiving chemotherapy [4]. Patients who receive immunosuppressive drugs in the present study represent 16.7% in post-COVID-19 patients AIFRS and 2.63% in patients with non-COVID-19. Although neutropenia is strongly associated with AIFRS (22.2%) in post-COVID-19, the vast majority of these patients have a hematological depletion.

In a study by Turner et al. [20] they found that 47.8% of their patients were diabetics, 39.0% having hematologic malignancies, 27.6% with corticosteroid use, 6.6% renal or liver failure, 6.3% organ transplantation, 2.3% AIDS, and 1.2% autoimmune disease.

These patients often have *Rhizopus oryzae* (44.4%) and *Aspergillus fumigatus* (33.3%) species isolated in post-COVID-19 patients and 18.4% & 26.3% in non-COVID-19 patients, respectively. There is an additional small subset of patients with a propensity to develop AIFRS. It is those who are iron overloaded or in renal failure and receive deferoxamine for iron chelation [4]. Some fungi (*Rhizopus*) can bind to deferoxamine that supply fungus with extra iron which aids its growth [21].

There is a role that suggests that diabetic patient's survival is better than patients with immunosuppression [19]. This has been attributed to the more easily optimized disease state. However, there is no evidence to suggest that the specific pathogen isolated can help inform prognosis. Other factors which appear to be related to a poorer prognosis include: older patients, aplastic anemia, delayed diagnosis, concurrent hepatorenal failure, intracranial complications and neutropenia [20,22].

Heard et al. [23] suggested COVID-19 fungal research investigate invasive *Candida* species as potential pathogens, the environmental factors such as rapid changes to ICU capacity and the infra-structure might increase the risk of COVID-19-associated respiratory aspergillosis, and the potential hazards of un-treating invasive aspergillosis.

The consolidation of a key demonstrative calculation is pivotal for recognizing obtrusive contagious illness in patients with COVID-19 who require critical-care and ought to be done as often as possible all through the period of serious respiratory trouble [24].

In our study we found that prolonged use of antibiotics, steroids, immunosuppressive drugs that may be used in treatment of COVID-19 exacerbate acute invasive fungal infection.

Mehta and Pandey [8] concluded that COVID-19 is associated secondary infections; both bacterial and fungal due to immune dysregulation. Additionally, the widespread use of steroids/monoclonal antibodies/broad-spectrum antibiotics as part of the armamentarium against COVID-19 may lead to the development/exacerbation of pre-existing fungal diseases.

Doctors ought to be mindful of the plausibility of invasive secondary fungal infections in patients with COVID-19 disease particularly in patients with preexisting risk factors and ought to empower early diagnosis

and treatment with the ensuing diminishment of mortality and morbidity. The use of medications should to be checked to attain a perfect dose in the shortest duration. The use of broad-spectrum antimicrobials should be re-evaluated.

Patients hospitalized in intensive care units (ICU) for COVID-19 share risk factors and underlying diseases reported for invasive fungal disease, corticosteroid therapy, intubation or mechanical ventilation, and cytokine storm were blamed [7].

Recent publications reported at least 10% of co-infection during COVID-19 in patients hospitalized in ICU for ARDS, among them *Aspergillus* infections [25]. Besides, the incidence of invasive pulmonary aspergillosis (IPA) in ICU patients admitted for severe influenza A and B is high reached 19% versus 5% in patients with severe pneumonia other than flu [26].

In addition, the pathophysiology of COVID-19 had co-morbidity with invasive fungal infection (IFI); first, the high aggressive feature of SARS-CoV-2 virus to the respiratory system made the IFI occurrence very likely, specifically those with airborne route of infection such as pneumocystosis and mucormycosis [27], second, absolute number of T lymphocytes, CD4+T and CD8+T cells are markedly lower in severe COVID-19 cases than in moderate cases, associated with markedly higher levels of IL-2R, IL-6, IL-10, TNF-alpha and some other inflammatory markers [28,29]. The complement system, while a first-line immune defense against invading pathogens, has off-target effects that lead to increases in inflammation, tissue damage, and thrombosis; these are common, life-threatening complications seen in patients with COVID-19 [30].

Turbin et al. [31] studied CT images for COVID-19 in sinusitis patients and found 2 cases characterized by dense and T1 hyperintense sinus substance, who accepted to speak to inspissated secretions and deposition of calcium salts or metals such as Mg, Mn and Fe, and typically seen with chronic invasive or allergic fungal sinusitis. However, they demonstrated features associated with acute invasive disease. Another case was characterized by hypodense, fluid signal contents, unlike the increased density seen with chronic invasive fungal sinusitis. Moreover, there was subtle involvement of the peri-antral fat, a finding relatively specific for invasive fungal sinusitis.

By comparing the number of patients of AIFRS in the last 4 years it is found that the number of patients increased up to triple in 2020. The increased number of AIFRS in 2020 is attributed to the increased number of COVID-19 with subsequent use of high dose of corticosteroid and immunosuppressant drugs and also to the immunological disturbance associated with COVID 19 infection.

5. Conclusions

The incidence of AIFRS is markedly more prominent in post-COVID-19 patients than in non-COVID-19 especially in immuno-compromised patients, diabetic, renal and liver dysfunction patients and patients with risk factors for rhinosinusitis.
