ABSTRACT

Aims It is unknown whether screen-detected atrial fibrillation (AF) carries cardiovascular risks similar to clinically detected AF. We aimed to compare clinical outcomes between individuals with screen-detected and clinically detected incident AF.

Methods We studied 8265 participants (age 49 ± 13 years, 50% women) without prevalent AF from the community-based Prevention of Renal and Vascular End-stage Disease (PREVEND) study. By design of the PREVEND study, 70% of participants had a urinary albumin concentration >10 mg/L. Participants underwent 12-lead ECG screening at baseline and every 3 years. AF was considered screen-detected when first diagnosed during a study visit and clinically detected when first diagnosed during a hospital visit. We analysed data from the baseline visit (1997–1998) up to the third follow-up visit (2008). We used Cox regression with screen-detected and clinically detected AF as time-varying covariates to study the association of screen-detected and clinically detected AF with all-cause mortality, incident heart failure (HF) and vascular events.

Results During a follow-up of 9.8 ± 2.3 years, 265 participants (3.2%) developed incident AF, of whom 60 (23%) had screen-detected AF. The majority of baseline characteristics were comparable between individuals with screen-detected and clinically detected AF. Unadjusted, both screen-detected and clinically detected AF were strongly associated with mortality, incident HF, and vascular events. After multivariable adjustment, screen-detected and clinically detected AF remained significantly associated with mortality (HR 2.21 (95% CI 1.09 to 4.47) vs 2.95 (2.18 to 4.00), p for difference=0.447) and incident HF (4.90 (2.28 to 10.57) vs 3.98 (2.49 to 6.34), p for difference=0.635). After adjustment, screen-detected AF was not significantly associated with vascular events, whereas clinically detected AF was (1.12 (0.46 to 2.71) vs 1.92 (1.21 to 3.06), p for difference=0.283).

Conclusion Screen-detected incident AF was associated with an increased risk of adverse outcomes, especially

Key questions

What is already known about this subject?

► Screening for atrial fibrillation (AF) improves early detection. However, it remains unclear whether individuals with screen-detected AF have a similar risk of adverse outcomes compared with patients with clinically detected AF.

What does this study add?

► In a large population-based cohort, screen-detected incident AF was associated with an increased risk of adverse outcomes, especially all-cause mortality and heart failure. There were no significant differences in risk between screen-detected AF and clinically detected AF.

How might this impact on clinical practice?

► Current guidelines make no distinction between screen-detected AF or clinically detected AF, and both are generally treated similarly. Given the findings of this study, this approach seems justifiable until ongoing AF screening trials provide more definitive answers. In addition, this study highlights that AF screening trials should focus not only on the prevention of stroke and mortality but also on the prevention of heart failure.

all-cause mortality and incident HF. The risk of outcomes was not significantly different between screen-detected AF and clinically detected AF.

INTRODUCTION

Atrial fibrillation (AF) is a major risk factor for mortality, heart failure (HF) and vascular events such as myocardial infarction (MI) and stroke.[1–3] Combined with an estimated lifetime risk of up to 1 in 3, and a prevalence

that is increasing even further due to rising life expectancy and rising prevalence of comorbidities, this makes AF a major healthcare challenge.[1 4]

Early detection and screening for AF are considered increasingly important, since effective therapies are available and early treatment of AF may improve outcomes.[5–9] Various screening strategies have been shown to increase the detection rate of AF.[10 11] Nevertheless, studies have yet to convincingly demonstrate that screening and subsequent treatment of AF can actually improve outcomes and prognosis.[12–14]

Despite the fact that unequivocal evidence from outcome trials is still lacking, European guidelines already recommend AF screening in individuals ≥65 years.[1] In addition, current guidelines make no distinction between patients with clinically detected AF and patients with screen-detected AF, and, therefore, recommend similar treatment for both groups.[1] However, it is unclear whether individuals with screen-detected AF are comparable to individuals with clinically detected AF, and whether they have a similar risk of mortality, HF and vascular events.[15] Therefore, we aimed to compare clinical characteristics and adverse outcomes between individuals with screen-detected AF and clinically detected AF.

METHODS

Study population and procedures

The study was performed with data from the PREVEND (Prevention of Renal and Vascular End-stage Disease) cohort study, which has been described in more detail elsewhere.[16 17] In short, PREVEND is a population-based cohort, which was designed to study if increased urinary albumin excretion is associated with renal and cardiovascular (CV) disease. From 1997 to 1998, 8592 community-dwelling individuals from the city of Groningen, The Netherlands were included in the study. A detailed overview of participant recruitment is provided in online supplemental figure S1. By design, approximately 70% of participants had a urinary albumin concentration (UAC) >10 mg/L, while the other 30% had a UAC <10 mg/L. At baseline, participants underwent various examinations, including anthropometric measurements, assessment of cardiometabolic risk factors, measurement of blood pressure and ankle brachial index and collection of blood and urine. Follow-up visits were performed every 3 years. A 12-lead ECG was made during the baseline visit and every follow-up visit. For the present study, we excluded participants with previously diagnosed AF based on hospital ECGs made prior to the date of inclusion (n=37), participants with AF on their baseline ECG (n=42) and participants without reliable ECG data (n=248), leaving 8265 participants. The PREVEND study was approved by the Medical Ethical Committee of the University Medical Center Groningen and was conducted in accordance with the Declaration of Helsinki. All participants provided written informed consent.

Ascertainment of AF

Incident AF was diagnosed if atrial fibrillation or flutter was present on a 12-lead ECG obtained during one of the three PREVEND follow-up visits or during an outpatient visit or hospital admission in either of the two hospitals that together cover the whole city of Groningen. All PREVEND ECGs from the baseline visit up to the third follow-up visit as well as all available hospital ECGs (including those obtained prior to study inclusion) were screened for AF using previously described methods,[18] which are summarised in the online supplemental notes. If first diagnosed at a PREVEND follow-up visit, AF was considered screen-detected. If first diagnosed during a hospital visit, AF was considered clinically detected. When participants had screen-detected AF, their general practitioner (GP) was informed. Further follow-up and treatment of AF were left at the discretion of the GP.

Clinical outcomes, risk factors and comorbidities

Information regarding vascular events was derived from the Dutch National Medical Registry, which contains hospital discharge diagnoses from all hospitals in the Netherlands.[18 19] Discharge diagnoses were coded according to the ninth revision of the International Classification of Diseases (ICD-9). Vascular events included acute MI and ischaemic heart disease (ICD-9 codes 410, 411), percutaneous transluminal angioplasty and bypass grafting of the coronary arteries or peripheral vessels (ICD-9 code 36) as well as haemorrhagic and ischaemic stroke (ICD-9 codes 433, 434). A committee of HF experts adjudicated all HF cases according to previously published criteria,[17] which are summarised in the online supplemental notes. Data on mortality were obtained through the municipal registration and Statistics Netherlands.[20] Risk factors and comorbidities (hypertension, diabetes, peripheral artery disease, history of MI, history of stroke and prevalent HF) were defined using previously described definitions for PREVEND,[18] which are described in the online supplemental notes.

Follow-up

The follow-up duration was calculated as the time between the baseline screening visit to the last contact date, death or 31 December 2008 (end of the third PREVEND follow-up visit), whichever came first.

Statistical analyses

Clinical characteristics at baseline were compared between participants with screen-detected AF and clinically detected AF. For continuous data, characteristics were compared using the independent samples t test for normally distributed data or Mann-Whitney U test for non-normally distributed data. For binary data, Pearson's χ^2 test or Fisher's exact test was used depending on sample size.

Incidence rates per 1000 person-years with 95% CIs were calculated for incident AF as well as the clinical outcomes of interest (death, incident HF and vascular

events). For AF, incidence rates were also calculated per age group and for men and women separately. For the outcomes, incidence rates were calculated separately for participants with screen-detected AF, participants with clinically detected AF and participants without AF. For the outcomes, separate incidence rates were also calculated for events occurring before AF and events occurring after AF.

Next, we used Cox regression models to assess the association of screen-detected AF and clinically detected AF with all-cause mortality, incident HF and vascular events. In order to account for the fact that events could occur prior to incident AF, screen-detected AF and clinically detected AF were entered into the Cox regression models as time-varying covariates. Thus, participants who developed incident AF were counted as participants *without* AF prior to the moment of AF diagnosis (non-exposed time) and were counted as participants *with* AF from the moment of AF diagnosis onwards (exposed time). For each outcome, we built three Cox regression models: (1) an unadjusted model including screen-detected AF and hospital-AF only, (2) model 1 additionally adjusted for age and sex and (3) model 2 additionally adjusted for relevant clinical characteristics (hypertension, diabetes, stroke, MI, peripheral artery disease, prevalent HF and natriuretic peptides).[18] In order to assess whether screen-detected AF was significantly more or significantly less associated with outcomes compared with clinically detected AF, we calculated p values for the difference in HRs between both AF types. The Cox proportional hazards assumption was assessed graphically using Kaplan-Meier curves for each outcome,[21] which revealed no violations of the proportional hazards assumption. For analyses with incident HF as the outcome, we excluded participants with prevalent HF (n=18). Given the design of PREVEND with overselection of individuals with microalbuminuria, all

Cox regression analyses were adjusted for baseline UAC. Analyses were performed using SPSS V.25. A p value <0.05 was considered statistically significant.

RESULTS
AF incidence and participant characteristics
The included PREVEND participants had a mean age of 49 ± 13 years, and 50% were women. During a mean follow-up duration of 9.8 ± 2.3 years, 265 individuals (3.2%) developed incident AF. Of all incident AF cases, 60 (23%) were screen-detected and 205 (77%) were clinically detected. In men, 26% of incident AF cases were screen-detected, compared with 15% for women (p=0.051). AF incidence rates were higher for older compared with younger participants, and for men compared with women (figure 1).

Compared with those with clinically detected AF, participants with screen-detected AF less often had peripheral artery disease or elevated natriuretic peptides (table 1). Otherwise, there were no significant baseline differences between participants with screen-detected and clinically detected AF.

Outcomes
During the follow-up period, 605 (7.3%) participants died, 262 (3.2%) developed incident HF and 806 (9.8%) had a vascular event. In the screen-detected AF group, 9 (15.0%) participants died, 11 (18.3%) developed incident HF and 12 (20.0%) had at least one vascular event. In the clinically detected AF group, 64 (32.2%) participants died, 71 (34.6%) developed incident HF and 100 (48.8%) had a vascular event.

In participants with clinically detected AF, the majority of incident HF cases and vascular events occurred prior to AF diagnosis, which was not the case in those with

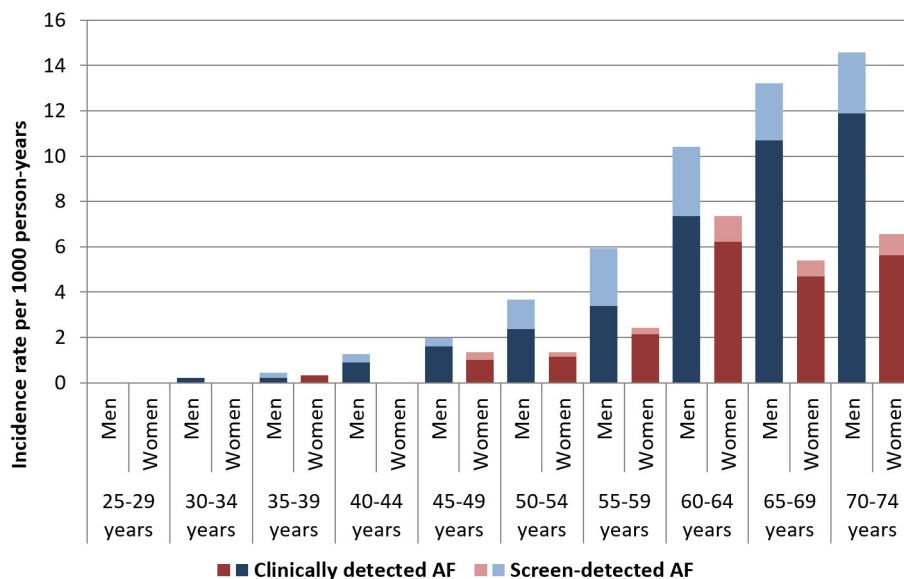

Figure 1 Incidence rates per 1000 person-years of screen-detected and clinically detected atrial fibrillation per age category in men and women. AF, atrial fibrillation.

Table 1 Clinical characteristics at baseline of the total study population and participants with screen-detected AF or clinically detected AF

Clinical characteristics	Total study population (n=8265)	Screen-detected AF (n=60)	Clinically detected AF (n=205)	P value
Male sex	4120 (50%)	48 (80%)	137 (67%)	0.051
Age	49 ± 13	60 ± 8	62 ± 9	0.163
BMI (kg/m^2)	26 ± 4	28 ± 5	28 ± 4	0.247
Hypertension	2613 (32%)	41 (68%)	138 (67%)	0.882
Diabetes	310 (4%)	4 (7%)	19 (9%)	0.562
History of MI	251 (3%)	5 (8%)	36 (18%)	0.084
History of stroke	81 (1%)	3 (5%)	6 (3%)	0.428
History of PAD	291 (4%)	2 (3%)	26 (13%)	0.032
Previously diagnosed HF	18 (0.2%)	1 (2%)	5 (2%)	1.000
NT-proBNP >125 ng/L	926 (11%)	18 (30%)	93 (45%)	0.048
eGFR <60 mL/min/1,73 m^2	466 (6%)	3 (5%)	18 (9%)	0.425
UAC ≥10 mg/L	5759 (70%)	45 (75%)	159 (78%)	0.679
CHA$_2$DS$_2$-VASc score	1.1 ± 1.0	1.5 ± 1.2	2.0 ± 1.1	0.192

Data presented as mean ± SD or count (%). P values represent the difference between participants with screen-detected AF and clinically detected AF.

screen-detected AF (figure 2). In both groups, coronary events (ie, events related to myocardial ischaemia) made up the majority of vascular events, and the incidence of stroke was relatively low (figure 3). Incidence rates for outcomes occurring after AF diagnosis were generally higher in participants with clinically detected AF than in participants with screen-detected AF, although CIs overlapped (figure 3).

In the unadjusted Cox regression analyses, both screen-detected AF and clinically detected AF were significantly associated with all-cause mortality, incident HF and vascular events. The corresponding HRs were not

Figure 2 Incidence of outcomes before and after diagnosis of atrial fibrillation. AF, atrial fibrillation; CD-AF, clinically detected atrial fibrillation; SD-AF, screen-detected atrial fibrillation.

significantly different between screen-detected AF and clinically detected AF (table 2).

After adjustment for age and sex, screen-detected AF was still significantly associated with all-cause mortality and incident HF, but not with vascular events. Clinically detected AF remained significantly associated with all three outcomes after adjustment for age and sex. There were no significant differences between the HRs of screen-detected AF and clinically detected AF (table 2).

After multivariable adjustment for risk factors and comorbidities, screen-detected AF remained significantly associated with all-cause mortality (HR 2.21, 95% CI 1.09 to 4.47) and incident HF (HR 4.90, 95% CI 2.28 to 10.57), but not with vascular events (HR 1.12, 95% CI 0.46 to 2.71). Clinically detected AF remained significantly associated with all-cause mortality (HR 2.95, 95% CI 2.18 to 4.00), incident HF (HR 3.98, 95% CI 2.49 to 6.34) and vascular events (HR 1.92, 95% CI 1.21 to 3.06). The multivariable adjusted HRs were not statistically different between screen-detected AF and clinically detected AF for all-cause mortality (p for difference=0.447), incident HF (p for difference=0.635) or vascular events (p for difference=0.283).
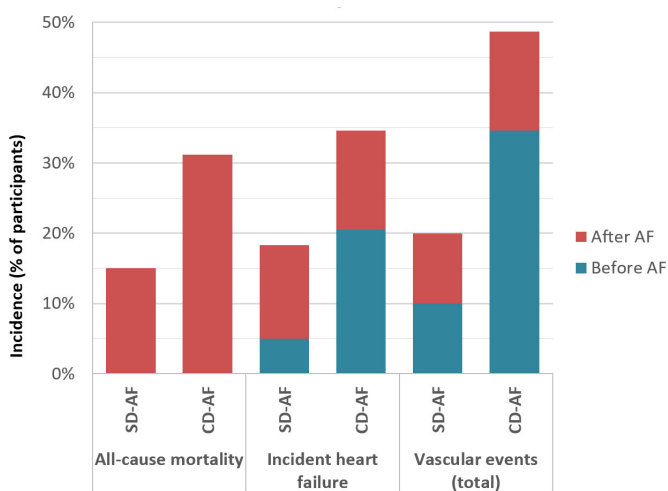

DISCUSSION

In this study, we demonstrated that screen-detected AF is associated with adverse outcomes, particularly all-cause mortality and incident HF, in participants from the population-based PREVEND study. We did not find significant differences between screen-detected AF and clinically detected AF in terms of their association with mortality, incident HF or vascular events.
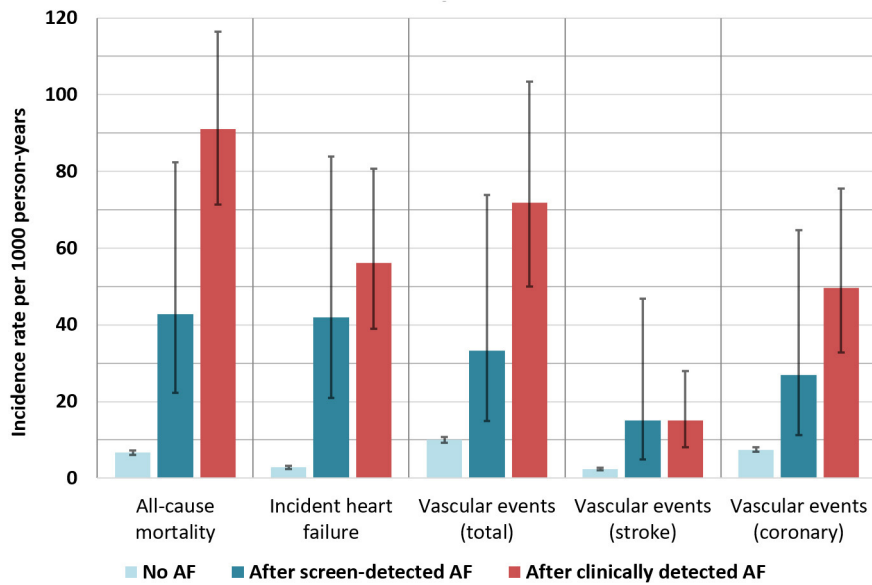

Figure 3 Outcome incidence rates per 1000 person-years after diagnosis of atrial fibrillation. AF, atrial fibrillation.

Outcomes in screen-detected AF

In recent years, a wide range of screening methods have been shown to improve early detection of AF.[10 11] While it is generally assumed that screen-detected AF is associated with adverse outcomes, only few studies have actually assessed the risk of adverse outcomes in screen-detected

Table 2 Association of screen-detected AF and clinically detected AF with outcomes

Outcomes	Time-varying covariate	HR (95% CI)	P value	HR(SD-AF) / HR(CD-AF) (95% CI)	P for difference
Model 1: unadjusted					
All-cause mortality	Screen-detected AF	5.66 (2.92 to 10.98)	<0.001	0.52 (0.26 to 1.06)	0.070
	Clinically detected AF	10.83 (8.23 to 14.26)	<0.001		
Incident heart failure	Screen-detected AF	12.10 (5.93 to 24.70)	<0.001	1.02 (0.45 to 2.29)	0.970
	Clinically detected AF	11.92 (7.63 to 18.61)	<0.001		
Vascular events	Screen-detected AF	3.27 (1.46 to 7.33)	0.004	0.73 (0.29 to 1.83)	0.505
	Clinically detected AF	4.47 (2.84 to 7.05)	<0.001		
Model 2: adjusted for age and sex					
All-cause mortality	Screen-detected AF	2.24 (1.16 to 4.36)	0.017	0.58 (0.29 to 1.16)	0.122
	Clinically detected AF	3.90 (2.96 to 5.13)	<0.001		
Incident heart failure	Screen-detected AF	5.16 (2.52 to 10.58)	<0.001	1.12 (0.50 to 2.53)	0.780
	Clinically detected AF	4.60 (2.93 to 7.21)	<0.001		
Vascular events	Screen-detected AF	1.24 (0.55 to 2.79)	0.598	0.64 (0.25 to 1.58)	0.330
	Clinically detected AF	1.96 (1.25 to 3.07)	0.003		
Model 3: adjusted for age, sex, prevalent heart failure, hypertension, diabetes, stroke, myocardial infarction, peripheral artery disease, and NT-proBNP					
All-cause mortality	Screen-detected AF	2.21 (1.09 to 4.47)	0.028	0.75 (0.35 to 1.58)	0.447
	Clinically detected AF	2.95 (2.18 to 4.00)	<0.001		
Incident heart failure	Screen-detected AF	4.90 (2.28 to 10.57)	<0.001	1.23 (0.52 to 2.92)	0.635
	Clinically detected AF	3.98 (2.49 to 6.34)	<0.001		
Vascular events	Screen-detected AF	1.12 (0.46 to 2.71)	0.802	0.58 (0.22 to 1.56)	0.283
	Clinically detected AF	1.92 (1.21 to 3.06)	0.006		

P values denote the significance of the time-varying covariates (screen-detected AF or clinically detected AF) in terms of their association with each clinical outcome (all-cause mortality, incident heart failure or vascular events). The P values for difference represent the difference in HRs between screen-detected AF and clinically detected AF.
AF, atrial fibrillation; CD-AF, clinically detected AF; NT-proBNP, N-terminal pro-brain natriuretic peptide; SD-AF, screen-detected AF.

AF, or studied how this risk compares to the risk in clinically detected AF.

In a recent pharmacy-based opportunistic screening study, which used single time point hand-held ECGs, the risk of all-cause mortality and CV hospitalisation was significantly higher in participants with screen-detected AF compared with those without AF, and there were no significant differences in risk between screen-detected AF and known prevalent AF.[22] Although we compared screen-detected AF with clinically detected incident AF (rather than prevalent AF), our findings seem to be in line with the results of this pharmacy-based screening study.

Other studies have mostly focused on outcomes in two populations that are somewhat different, yet related to our population with screen-detected AF: (1) patients with subclinical AF (SCAF) and atrial high-rate episodes (AHRE) as detected by cardiac implantable electronic devices (CIEDs) and (2) patients with asymptomatic (silent) AF.

Studies in patients with CIEDs, such as the Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial (ASSERT), have demonstrated that SCAF/AHRE is associated with vascular events, HF hospitalisation and mortality.[23–26] Our results seem largely in line with these studies. However, comparisons between SCAF/AHRE and screen-detected AF should be made with caution, since patients with CIEDs may be different from the general AF population.[27]

Studies in asymptomatic AF are also relevant to the topic of screen-detected AF, since individuals with screen-detected AF are frequently asymptomatic.[27–30] In the EurObservational Research Programme - Atrial Fibrillation (EORP-AF) registry, patients with asymptomatic AF had a substantially higher risk of mortality compared with their symptomatic counterparts, although it has to be noted that asymptomatic patients were less often treated with oral anticoagulants (OACs).[31] By contrast, in patients with persistent AF from the RAte Control versus Electrical cardioversion for persistent atrial fibrillation (RACE) study, asymptomatic AF was associated with a lower risk of CV morbidity and mortality than symptomatic AF, although the difference may in part have been caused by the lower prevalence of HF in the asymptomatic group.[32] Our findings seem more in line with recent results from the Global Anticoagulant Registry in the Field - Atrial Fibrillation (GARFIELD-AF) study, which found no difference in outcomes between asymptomatic and symptomatic patients with at least one stroke risk factor.[33] Importantly, studies in asymptomatic AF have some limitations when applied to the setting of AF screening. First, many of these studies were performed in selected (mostly hospital-based) populations, which may be different from the general population targeted with screening. Furthermore, not all individuals with screen-detected AF are asymptomatic: in the population-based Lifelines study, which used single time point ECG

screening similar to PREVEND, palpitations were in fact a major independent predictor of previously undiagnosed AF.[34]

After multivariable adjustment, screen-detected AF remained significantly associated with all-cause mortality and incident HF, but not with vascular events. This might be due to the small number of vascular events, particularly stroke, that occurred in participants with screen-detected AF. The low incidence of stroke seems consistent with previous AF screening trials[22 27] and could possibly be explained by initiation OACs after diagnosis of screen-detected AF. Based on our data, we cannot draw definitive conclusions about the risk of stroke and other vascular events in (untreated) screen-detected AF. However, recently published results from the STROKESTOP II trial indicate that AF screening and subsequent treatment initiation may lead to a modest, yet significant reduction of stroke incidence in the general population.[35]

Overall, in our study, the association of screen-detected AF with incident HF was stronger than its association with mortality and vascular events. This highlights that future studies should focus not only on preventing stroke and mortality but also on preventing HF in patients with screen-detected AF.[24]

Clinical characteristics of individuals with screen-detected AF and clinically detected AF

Another aim of our study was to compare clinical characteristics between individuals with screen-detected and clinically detected AF. We found that both groups had largely similar baseline characteristics, with only a few differences. Participants with clinically detected AF had higher natriuretic peptide levels at baseline, which may indicate that they were more likely to have previously unrecognised or subclinical HF at baseline, and that AF may have been detected during hospital visits for HF. Indeed, in participants with clinically detected AF, the majority of incident HF cases were diagnosed prior to AF. By contrast, HF was mostly diagnosed after AF in participants with screen-detected AF. Furthermore, the higher proportion of women in the clinically detected AF group seems in line with previous studies in symptomatic versus asymptomatic AF, which have consistently demonstrated that patients with symptomatic AF are more likely to be women compared with asymptomatic individuals.[31–33]

Strengths and limitations

Our study was performed in a large population-based cohort with almost 10 years of follow-up and solid validation of incident AF and endpoints. Due to the linkage with hospital registries, we were able to provide a reliable and direct comparison between screen-detected and clinically detected AF.

Limitations include the lack of data about type of AF (paroxysmal, persistent or permanent) and symptoms. This information should be taken into account in future studies, as it may help explain why AF remains unrecognised in some but not in others. During the three-yearly

PREVEND visits, only single time point ECGs were made, and, therefore, cases of paroxysmal AF may have been missed. Although the use of ICD-9-based discharge codes from the Dutch National Medical Registry has been shown to be highly reliable,[18 36] we cannot fully rule out that some vascular outcomes were missed or misclassified. Data on the primary reason for the hospitalisations or outpatient visits during which AF was diagnosed were not available. Furthermore, data regarding medication use during follow-up were unavailable: since OACs may have been initiated in a large proportion of individuals with incident AF, the incidence of vascular events in our study was likely an underestimation. Since we used data up to 2008, results might be different in the present-day setting due to advances in the treatment of AF in recent years. Finally, the PREVEND cohort is predominantly Caucasian and enriched for microalbuminuria, which may limit generalisability.

CONCLUSIONS

This study demonstrates that individuals with screen-detected AF are at increased risk of adverse outcomes, particularly all-cause mortality and incident HF. We did not find significant differences in risk between screen-detected and clinically detected AF. However, randomised trials are needed to assess if outcomes can be improved by treating individuals with screen-detected AF similarly to patients with clinically detected AF. Our results highlight that AF screening trials should focus not only on the prevention of stroke and mortality but also on the prevention of HF in individuals with screen-detected AF.
