Impaired oxidative stress response characterizes HUWE1-promoted X-linked intellectual disability

Matthias Bosshard¹, Rossana Aprigliano^{1,2}, Cristina Gattiker¹, Vuk Palibrk², Enni Markkanen¹, Paul Hoff Backe³, Stefania Pellegrino¹, F. Lucy Raymond⁴, Guy Froyen⁵, Matthias Altmeyer¹, Magnar Bjørås^{2,3,6}, Grigory L. Dianov^{7,8} & Barbara van Loon^{1,2,6}

Mutations in the HECT, UBA and WWE domain-containing 1 (*HUWE1*) E3 ubiquitin ligase cause neurodevelopmental disorder X-linked intellectual disability (XLID). *HUWE1* regulates essential processes such as genome integrity maintenance. Alterations in the genome integrity and accumulation of mutations have been tightly associated with the onset of neurodevelopmental disorders. Though *HUWE1* mutations are clearly implicated in XLID and *HUWE1* regulatory functions well explored, currently much is unknown about the molecular basis of *HUWE1*-promoted XLID. Here we showed that the *HUWE1* expression is altered and mutation frequency increased in three different XLID individual (*HUWE1* p.R2981H, p.R4187C and *HUWE1* duplication) cell lines. The effect was most prominent in *HUWE1* p.R4187C XLID cells and was accompanied with decreased DNA repair capacity and hypersensitivity to oxidative stress. Analysis of *HUWE1* substrates revealed XLID-specific down-regulation of oxidative stress response DNA polymerase (Pol) λ caused by hyperactive *HUWE1* p.R4187C. The subsequent restoration of Pol λ levels counteracted the oxidative hypersensitivity. The observed alterations in the genome integrity maintenance may be particularly relevant in the cortical progenitor zones of human brain, as suggested by *HUWE1* immunofluorescence analysis of cerebral organoids. These results provide evidence that impairments of the fundamental cellular processes, like genome integrity maintenance, characterize *HUWE1*-promoted XLID.

Intellectual disability (ID) is a complex neurodevelopmental condition that results in arrested or incomplete development of the mind^{1,2}. It manifests before the age of 18 and has an estimated 2% prevalence in the Western world population. X-linked ID (XLID) is a subset of ID's associated with alterations in over 100 different genes located on the X chromosome. To date more than twenty XLID families harboring either a submicroscopic duplication or specific missense mutations in the HECT, UBA and WWE domain-containing 1 (*HUWE1*) gene have been identified³⁻⁷. *HUWE1*-promoted XLID is characterized by high clinical heterogeneity, ranging from dysmorphic facial features and mild ID, to microcephaly, extreme ID, deafness, joint contractures and incontinence³.

HUWE1 encodes for an 482-kDa E3 ubiquitin ligase⁸. Through poly-ubiquitination *HUWE1* regulates numerous substrates, predominantly predisposing them for proteasomal degradation. In addition to its substrates, *HUWE1* also mediates selfubiquitination; this is counteracted by Ser18-containing isoform of ubiquitin-specific-processing protease 7 (USP7S) that de-ubiquitinates *HUWE1* and prevents its subsequent degradation⁹⁻¹¹. By poly-ubiquitinating p53 and the important DNA damage response factors, like Cdc6 and DNA polymerases (Pols) λ and β , *HUWE1* contributes to the maintenance of genome integrity^{8,12,13}. Loss of *HUWE1* was recently shown to cause increased genome instability¹⁴. Interestingly, growing number of evidence indicates

that the genome integrity maintenance mechanisms are of key importance for the neuronal development¹⁵ and mutations in DNA repair genes have been identified as causative in IDs^{16,17}.

Huwe1 is critical developmental gene and its total loss leads to embryonic lethality in mice¹⁸. Conditional *Huwe1* inactivation in the mouse brain results in disorganization of laminar cortex patterning causing neonatal lethality^{18,19}. Studies with the conditional *Huwe1* mice further underline the specific importance of HUWE1 for neuronal development, in particular for the initiation of cell cycle exit and start of neuronal differentiation in the brain²⁰. In the mouse adult hippocampus HUWE1 is required for proliferating neural stem cells (NSCs) to return to quiescence²¹. Many of human XLID-causing HUWE1 mutations reside within, or are in the close vicinity of the catalytic HECT domain (p.R2981H, p.R4013W, p.R4187C and p.G4310R)^{3,5}. Very recent work in *C. elegans* suggested that mutations corresponding to p.R2981H and p.R4187C potentially alter HUWE1 function²². Further, we showed that the levels of mutated HUWE1 p.G4310R are significantly lower in XLID individual cells when compared to cells from healthy individual³. Currently it remains however unknown, if other XLID-associated mutations result in similarly changed HUWE1 levels, as well as what is the impact of potentially altered expression and function on the HUWE1-regulated processes, such as genome integrity maintenance. Taken together, though HUWE1 mutations are clearly implicated in XLID and HUWE1 regulatory functions well explored, much is unknown about the cellular processes that are altered by XLID-causing HUWE1 and that contribute to the onset of the disease.

In this study we addressed how mutated HUWE1 contributes to XLID development. Our results revealed increased mutation frequency in three different HUWE1-promoted XLID individual cell lines (with HUWE1 p.R2981H or p.R4187C, and *HUWE1* duplication). Mutation frequency was highest in the HUWE1 p.R4187C XLID cells and was accompanied with a decreased DNA repair capacity and hypersensitivity to oxidative stress. While accumulation of *de novo* mutations was previously shown to negatively affect functioning of developmental genes²³, increased oxidative stress was suggested to have particular pathophysiological role in neurodevelopmental disorders, including XLID^{24,25}. Immunoblot analysis of HUWE1 targets showed an XLID-specific down-regulation of oxidative stress response enzyme Pol λ that was caused by the hyperactive HUWE1 p.R4187C. Further, use of a small molecule USP7 inhibitor in XLID cells and consequent restoration of Pol λ levels counteracted the oxidative hypersensitivity. Analysis of cerebral organoids indicated a specific localization of human HUWE1 in structures resembling human cortical progenitor regions, thus supporting the role of HUWE1 in neurodevelopment. Based on these findings we propose that the XLID-specific HUWE1 p.R4187C results in increased mutation frequency and impaired oxidative stress response. These alterations may be particularly relevant in cortical progenitor zones and contribute to the XLID onset.

Results

Altered HUWE1 protein levels are accompanied with increased mutation frequency in XLID individual cells. To address how XLID-specific *HUWE1* mutations and duplication affect the protein levels immunoblot analysis using lymphoblastoid cell lines (LCLs) derived from a healthy individual and three different XLID donors, harboring duplicated *HUWE1*, HUWE1 p.R4187C, or HUWE1 p.R2981H, was performed. While HUWE1 levels were significantly lower in XLID cells with HUWE1 p.R4187C, they were higher in the cells with HUWE1 p.R2981H or duplicated *HUWE1*, when compared to the healthy individual cells (Fig. 1a,b). This indicated that HUWE1 protein levels are altered in XLID individual cells. Since alterations in the HUWE1 levels result in increased genome instability¹⁴, and accumulation of genomic mutations has been associated with the onset of neurodevelopmental disorders, we next tested if the observed alterations in the HUWE1 levels affect the mutation frequency in XLID cells by using the *PigA*-mutation frequency assay²⁶. A strong increase in the mutation rate was observed in all three XLID cell lines (Fig. 1c). Interestingly, the highest increase in the mutation frequency was detected in the XLID cells with the HUWE1 p.R4187C (Fig. 1c), which is expressed at a lower level than HUWE1 wild-type (WT) protein (Fig. 1a,b). Taken together, our findings indicate that the XLID associated genetic alterations affect HUWE1 expression and result in increased genome instability.

Protein levels of HUWE1 substrate DNA polymerase λ are specifically downregulated in XLID cells. To determine if increased mutation rate is caused by dysregulation of HUWE1 substrates, which play a role in genome maintenance, an immunoblot screen was performed in healthy individual and XLID cells. From three tested XLID LCLs, HUWE1 p.R4187C cells with highest mutation frequency (Fig. 1c) were chosen for the subsequent analysis (hereafter referred to as XLID individual cells). A significant change in the protein levels of two HUWE1 substrates was observed; Pol λ levels were downregulated, while Cdc6 was upregulated in XLID individual cells (Figs 2a,b and S1). The protein levels of other analyzed HUWE1 substrates involved in genome maintenance: MUTYH (MutY homologue), p53, TopBP1 (DNA topoisomerase 2-binding protein (1)), BRCA1 (BRCA1, DNA repair associated), HDAC2 (histone deacetylase (2)) and c-Myc (v-myc avian myelocytomatosis viral oncogene homolog) did not significantly differ between healthy and XLID individual cells (Fig. S2).

To test if the observed changes in Pol λ and Cdc6 occur on the posttranslational level and potentially directly correlate with the HUWE1 p.R4187C, mRNA levels were analyzed next. While no difference in the Pol λ mRNA amounts was observed (Fig. 2c), Cdc6 mRNA levels were significantly upregulated in XLID cells when compared to healthy individual (Fig. S2). This suggests that Pol λ dysregulation occurs directly on the posttranslational level, and is potentially caused by mutated HUWE1 p.R4187C E3 ubiquitin ligase. In contrast to Pol λ , dysregulation of Cdc6 is an indirect result of changes at the level of transcription.

HUWE1 p.R4187C, mutated in XLID, hyperubiquitinates Pol λ and predisposes it for proteasomal degradation. To test if Pol λ dysregulation is caused directly by mutated HUWE1 p.R4187C, healthy and XLID individual cells with stably knocked down HUWE1 were generated. Interestingly, upon the HUWE1 knockdown in XLID individual cells Pol λ levels were rescued back to the ones observed in the healthy individual

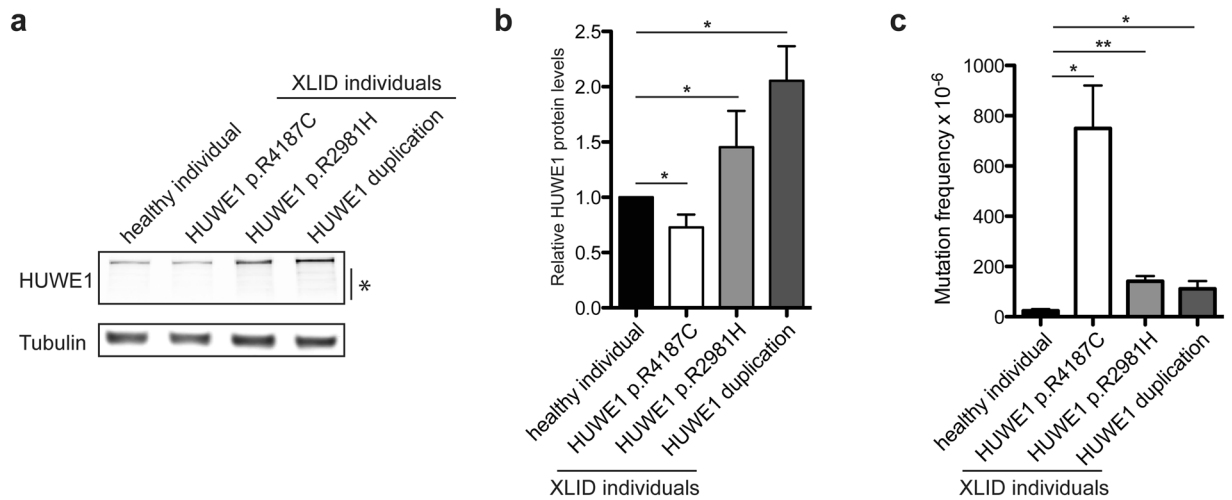

Figure 1. HUWE1 protein levels are altered and mutation frequency increased in HUWE1-promoted XLID cells. **(a)** Immunoblot analysis of HUWE1 protein levels in healthy and the three indicated HUWE1-promoted XLID individual cell lines harboring duplicated HUWE1, HUWE1-R4187C or HUWE1-R2981H. Asterisk indicates unspecific bands. **(b)** Quantification of **(a)** ($n = 3$). Error bars indicate mean \pm SD. The difference in the HUWE1 expression between healthy individual and XLID cells was determined by unpaired t-test, two-tailed p-value; * $p < 0.05$ and ** $p < 0.01$ – HUWE1 p.R4187C, $t(4) = 4.08$ $p = 0.0151$; HUWE1 p.R2981H, $t(4) = 3.05$ $p = 0.0381$; HUWE1-duplication $t(4) = 4.08$ $p = 0.0151$. **(c)** Endogenous mutation frequency in healthy and three XLID individuals assessed by the PigA-mutation frequency assay ($n = 3$). Error bars indicate mean \pm SEM. The significance of mutation frequency change between genotypes was determined by unpaired t-test, two-tailed p-value; * $p < 0.05$ and ** $p < 0.01$ – HUWE1 p.R4187C, $t(4) = 4.24$ $p = 0.0133$; HUWE1 p.R2981H, $t(4) = 5.32$ $p = 0.006$; HUWE1-duplication $t(4) = 2.81$ $p = 0.0486$.

cells (Fig. 2d,e), suggesting that Pol λ levels are directly modulated by HUWE1 p.R4187C. Similarly, and in line with previous findings¹³, knockdown of HUWE1 in the healthy individual cells led to Pol λ accumulation (Fig. 2d,e). To address if the HUWE1-caused changes in Pol λ levels were mediated via subsequent proteasomal degradation, healthy and XLID individual cells were treated with a proteasomal inhibitor MG132. The MG132 treatment resulted in stabilization and significant increase of the Pol λ protein levels both in healthy and XLID individual cells (Fig. 2f,g). This indicated that HUWE1 p.R4187C downregulates Pol λ levels in XLID individual cells by predisposing it for proteasomal degradation. Next, to determine if Pol λ downregulation is a result of altered HUWE1 activity caused by p.R4187C mutation, which resides within catalytic HECT domain, *in vitro* ubiquitination assays were performed. The activity of $\Delta 2906$ HUWE1 WT and p.R4187C was compared in reactions with purified human Pol λ , E1 and E2 enzymes. Interestingly, HUWE1 p.R4187C more efficiently ubiquitinated Pol λ than HUWE1 WT (Fig. 2h,i), thus suggesting that p.R4187C mutation renders HUWE1 hyperactive. These findings are supported by the observed reduction in HUWE1 and Pol λ levels in XLID individual cells (Figs 1a and 2a), since increased ubiquitination of the two proteins results in promoted proteasomal degradation^{9–11,13}. To further explore the importance of the amino acid R4187, structural analysis of recently published C-terminal HUWE1 structure²⁷ was performed (Fig. 2j). The HUWE1 C-terminal HECT domain adopts a bilobal structure, with the C-terminal lobe containing the catalytic cysteine that participates in the transfer of ubiquitin to substrate, and the N-terminal lobe representing the E2 binding domain. In this uncomplexed structure of the C-terminal HECT domain, the affected R4187 residue is located in the beta hairpin within the E2-binding region in the N-terminal lobe. As shown in Fig. 2j, the R4187 stretches towards the helical core of the protein and is engaged in several hydrogen bonds. A R4187C mutation will likely affect the interaction with the E2 enzymes and consequently influence the ubiquitin transfer. In summary, these findings indicate that the HUWE1 p.R4187C is hyperactive towards Pol λ , resulting in XLID-specific Pol λ downregulation.

Oxidative stress response is impaired in XLID individual cells. Our findings indicate that XLID individual cells have increased mutation frequency and reduced Pol λ levels (Figs 1 and 2). Interestingly, Pol λ has been suggested to play an important role in mutagenesis by counteracting C:G \rightarrow A:T transversion mutations that arise from the frequent oxidative lesion 7,8-dihydro-8-oxo-guanine (8oxoG)^{13,28–31}. Lack of Pol λ was shown to cause increased misincorporation of dATP and reduced incorporation of dCTP opposite 8oxoG. This leads to accumulation of A:8oxoG mispairs that subsequently give rise to C:G \rightarrow A:T mutations in the next round of replication, or undergo futile cycles of DNA repair with toxic single strand breaks as byproducts³². To determine if reduced Pol λ levels in XLID individual cells affect 8oxoG bypass fidelity an *in vitro* DNA polymerase assay was performed (Fig. 3a,b). A Pol λ -specific DNA substrate that contains a single nucleotide gap facing an 8oxoG lesion in the complementary strand was used. As indicated in Fig. 3a the incorporation of dCTP decreased, while misincorporation of dATP increased in the XLID whole cell extracts (WCEs), when compared to extracts from healthy individual cells. The observed differences were most significant at the lower dNTP concentrations: 1 μ M and 5 μ M dATP and 1 μ M dCTP (Fig. 3b), which is consistent with the role of Pol λ in gap filling at lower dNTP

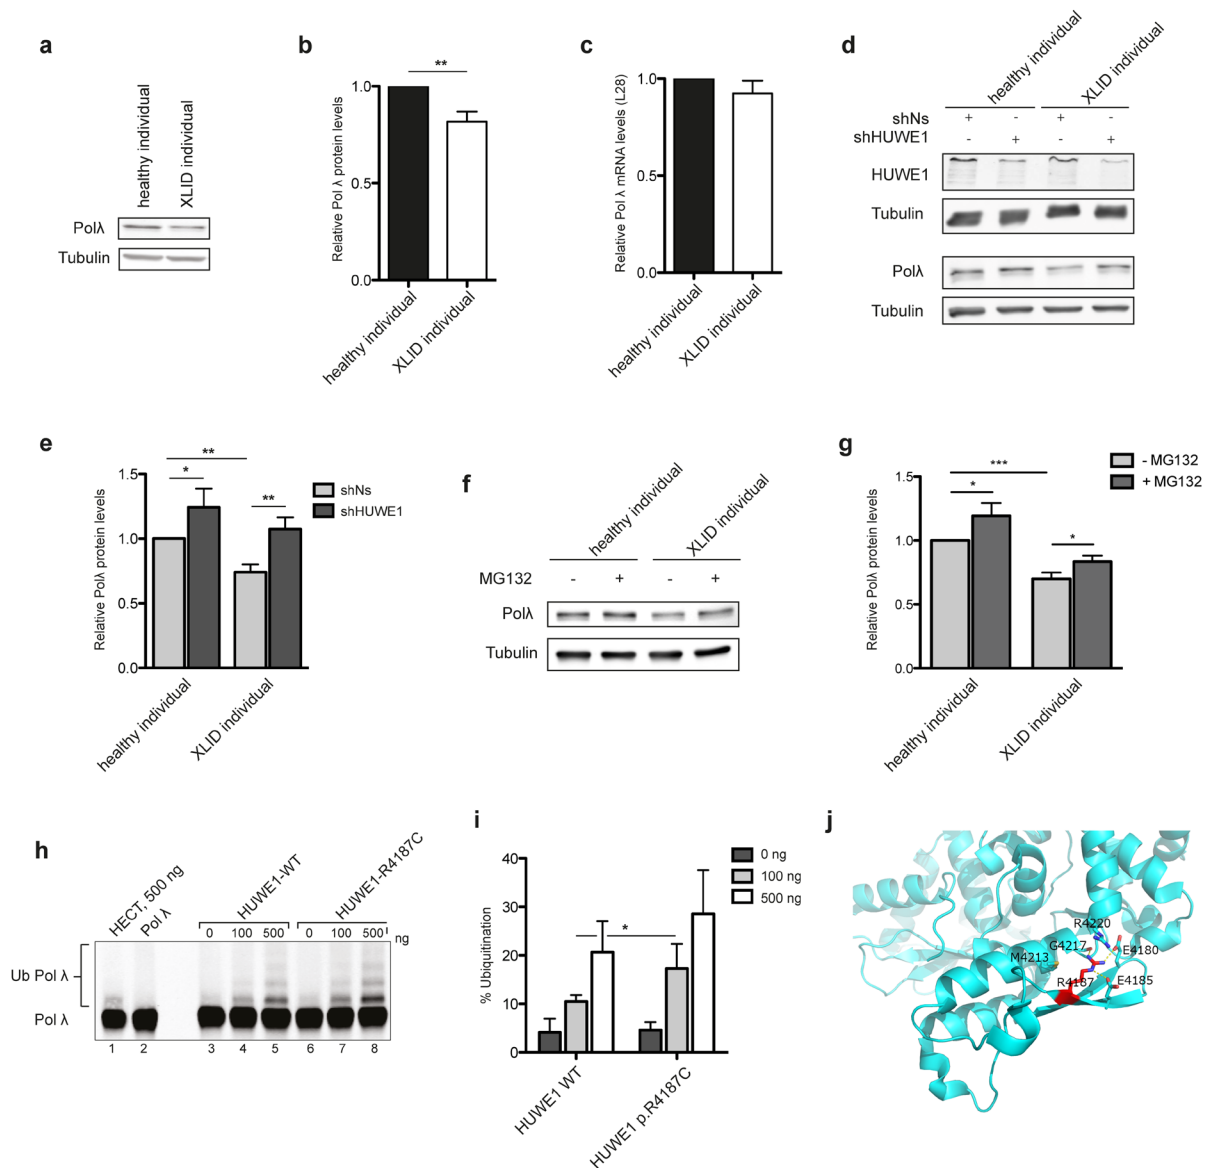

Figure 2. Cellular pool of HUWE1 substrate DNA polymerase λ is specifically reduced in XLID individual cells through HUWE1 p.R4187C hyperubiquitination. **(a)** Immunoblot analysis of the DNA polymerase (Pol) λ levels in healthy and XLID individual (HUWE1-R4187C) cells. **(b)** Quantification of **(a)** ($n = 3$). Error bars indicate mean \pm SD. The significance of protein level changes was determined by unpaired t-test, two-tailed p-value; $**p < 0.01$ – Pol λ ($t(4) = 6.06$ $p = 0.0037$). **(c)** mRNA levels of Pol λ in healthy and XLID individual cells addressed by RT-qPCR ($n = 3$). Figure 3. Oxidative stress response is impaired in HUWE1 p.R4187C XLID individual cells. **(a)** Efficiency and accuracy of dATP versus dCTP incorporation opposite frequent oxidative DNA lesion 7,8-dihydro-8-oxo-guanine (G^{oxo}), using increasing amounts of healthy and XLID individual (HUWE1-R4187C) whole cell extracts (WCEs) in an *in vitro* DNA polymerase assay. **(b)** Quantification of **(a)** ($n = 5$). Error bars indicate mean \pm SEM. The significance of changes between healthy and XLID individual WCEs was determined by unpaired t-test, one-tailed p-value; * $p < 0.05$ -1 μ M dATP $t(7) = 2.29$ $p = 0.0277$; 5 μ M dATP $t(8) = 2.11$ $p = 0.034$; 1 μ M dCTP $t(7) = 2.4$ $p = 0.0238$. **(c)** Cell viability of healthy and XLID individual (HUWE1-R4187C) cells after 24 hours of continuous treatment with increasing concentrations of potassium bromate ($KBrO_3$) ($n = 3$). The significance of changes in the survival upon the treatment was determined by unpaired t-test, two-tailed p-value; $n.s. \geq 0.05$, * $p < 0.05$ and ** $p < 0.01$. **(d)** Single-cell gel electrophoresis (Comet) analysis of DNA repair kinetics upon H_2O_2 -treatment in healthy and XLID individual cells, represented as the relative percentage of DNA in the tail. Mean of 3 independent experiments presented. In each experiment at least 100 cells were analyzed per each time point and each cell type. Error bars indicate mean \pm SEM.

concentrations³³. Taken together these data indicate that the presence of oxidative base damage 8oxoG in the genome of HUWE1-promoted XLID cells has high mutagenic potential that is accompanied with reduced Pol λ levels. In addition to increased inaccurate 8oxoG bypass, reduction in Pol λ levels was shown to cause hypersensitivity to oxidative stress²⁹. To test if XLID individual cells with reduced Pol λ levels have altered sensitivity to oxidative stress, potassium bromide ($KBrO_3$) treatment was performed and viability determined. The XLID individual cells were hypersensitive to oxidative stress induced by $KBrO_3$, when compared to the cells from healthy individual (Fig. 3c). The hypersensitivity of XLID cells was oxidative stress-specific, as no difference in the sensitivity to alkylation treatment was detected between healthy and XLID individual cells (Fig. S3). Subsequent Comet analysis showed increased accumulation of toxic single and double strand breaks as well as labile abasic (AP) sites at all time points after exposure to the oxidizing agent hydrogen peroxide (H_2O_2) in the XLID cells as compared to healthy individual cells (Fig. 3d). In summary, these findings indicate that exposure to oxidative stress results in hypersensitivity of HUWE1 p.R4187C XLID individual cells, potentially caused by accumulation of DNA breaks and labile AP sites.

Inhibition of USP7 efficiently reverses the oxidative stress hypersensitivity of XLID cells.

HUWE1 levels are directly regulated by USP7S that efficiently de-ubiquitinates HUWE1 and prevents its subsequent degradation¹⁰. We hypothesized that by inhibiting USP7S it would be possible to promote HUWE1 p.R4187C degradation and consequently stabilize Pol λ , as well as rescue the defects observed in XLID cells, like hypersensitivity to oxidative stress. To test this hypothesis, healthy and XLID individual cells were treated with P5091, a USP7 inhibitor (USP7i) currently in preclinical trials³⁴. Treatment with USP7i resulted in decreased HUWE1 protein levels (Fig. 4a) as well as stabilization and increase in Pol λ protein levels (Fig. 4b) both in healthy and XLID individual cells. Importantly, besides the impact on the protein level, USP7i treatment resulted in reversal of the XLID hypersensitivity to the oxidizing agent $KBrO_3$ to the level comparable to the healthy individual cells (Fig. 4c). These findings support the idea that the hypersensitivity to oxidative stress observed in XLID individual cells is directly caused by HUWE1 p.R4187C, potentially through Pol λ .

Human HUWE1 localizes in the regions resembling cortical progenitor zones. Several studies using mouse models demonstrated an essential role of HUWE1 in murine neurodevelopment^{18,20}. Currently it is however not clear where in the human brain HUWE1 localizes and to which extent it contributes to human neurodevelopment. To explore HUWE1 distribution in human cortical structures and to obtain insight in which

Figure 4. USP7 inhibition reverses the XLID-specific hypersensitivity to oxidative stress. **(a)** Immunoblot analysis of HUWE1 and Polλ protein levels in healthy and XLID individual (HUWE1-R4187C) cells treated for 24 hours with 8 μM P5091, the USP7 inhibitor (USP7i), or DMSO as a control. Asterisk indicates unspecific bands. **(b)** Quantification of **(a)** ($n = 3$). **(c)** Cell viability of healthy and XLID individual cells pretreated for 24 hours with 8 μM USP7i or DMSO as a control, followed by a continuous 24 hour treatment with increasing concentrations of potassium bromate (KBrO₃) ($n = 3$). Error bars indicate mean \pm SD. The significance was determined by unpaired t-test, two-tailed p-value; ** $p < 0.01$ and *** $p < 0.001$ –5 mM KBrO₃ (healthy individual vs healthy individual + USP7i) $t(4) = 5.96$ $p = 0.004$, (XLID individual vs XLID individual + USP7i) $t(4) = 13.59$ $p = 0.0002$; 7.5 mM KBrO₃ (healthy individual vs healthy individual + USP7i) $t(4) = 8.23$ $p = 0.0012$, (XLID individual vs XLID individual + USP7i) $t(4) = 6.42$ $p = 0.003$.

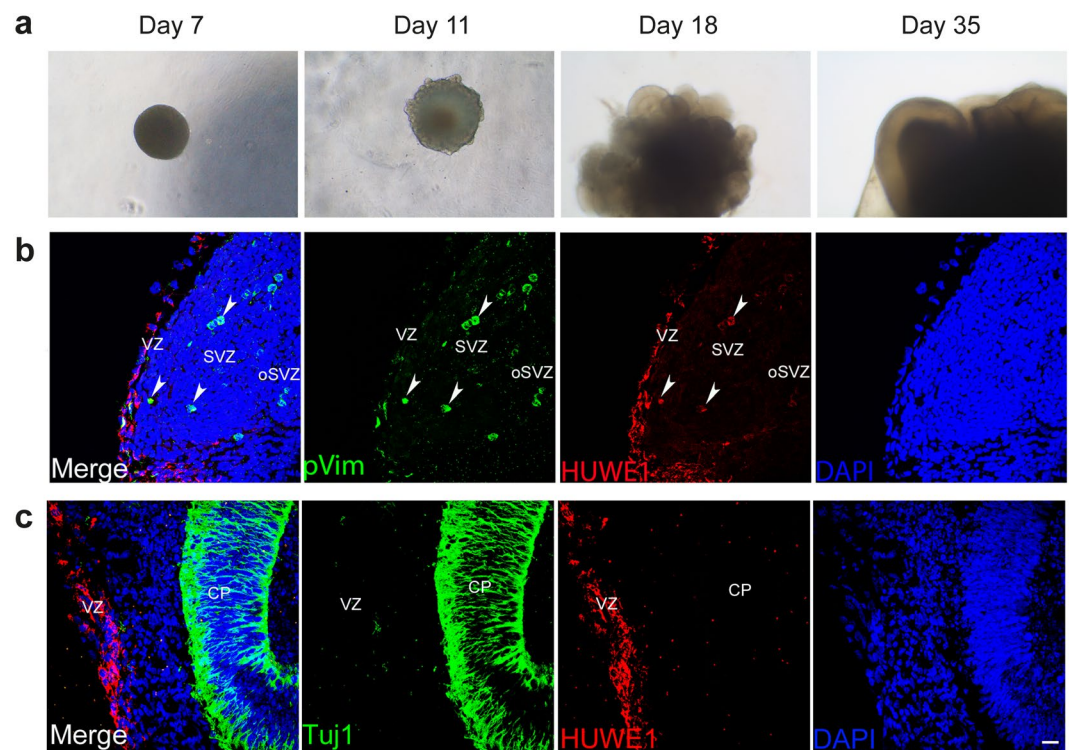

Figure 5. Human HUWE1 localizes in ventricular and subventricular zones. **(a)** Representative bright-field images of cerebral organoids at 7, 11, 18 and 35 days of differentiation. **(b,c)** Confocal microscope images of 35-days old cerebral organoids stained with DAPI, and antibodies against HUWE1, Phospho-vimentin (pVim) a marker of radial glia cells **(b)**, and Tuj1 a marker of differentiated neurons **(c)**. HUWE1 co-localizes with pVim (arrowheads) in ventricular (VZ), subventricular (SVZ) and outer SVZ (oSVZ), but not with Tuj1 in cortical plate (CP). Scale bar, 10 μm.

regions HUWE1 misregulation could particularly contribute to the development of XLID, we developed cerebral organoids by differentiating healthy individual hiPSCs (Fig. 5a). Immunofluorescence analysis of 35-days old cerebral organoids revealed that human HUWE1 is mainly expressed in cortical progenitor regions, resembling ventricular and sub-ventricular zones (VZ and SVZ, respectively) (Fig. 5b). Further HUWE1 co-localized with phospho-Vimentin (pVim), a marker of mitotic radial glia, NSCs. Interestingly, in 35-days old organoids HUWE1 was not detectable in the Tuj1 positive neurons (Fig. 5c). These results suggest that human HUWE1 localizes in the regions resembling cortical progenitor zones where, through its essential role in neurodevelopment, could contribute to the onset of XLID.

Discussion

Mutations in more than 100 XLID-causing genes have been identified during four decades of research. Besides high genetic variability, a high clinical heterogeneity has been reported in individuals with different XLID syndromes². The high degree of heterogeneity and limited number of individuals with identical mutations in XLID causative genes present a particular challenge for identification of molecular processes altered in XLID. In this study we identified cellular pathways impaired in XLID cells and define regions resembling human cortex that are potentially most affected by mutated HUWE1. Our findings show that XLID-causing *HUWE1* mutations lead to alterations in HUWE1 protein levels and result in increased mutation frequency in particular in XLID cells with reduced HUWE1 levels (Fig. 1). This is in line with a very recent observation that loss of HUWE1 causes genome instability¹⁴. The increase in the mutation frequency, observed in XLID cells, similar to previous studies^{35,36}, suggests that the rate of *de novo* mutations may be higher in individuals with XLID than in healthy individuals. Further by analyzing HUWE1 substrates involved in genome maintenance we observe a specific downregulation of DNA repair enzyme Pol λ on posttranslational level by hyperactive HUWE1 p.R4187C (Fig. 2). The observation that p.R4187C mutation results in altered HUWE1 activity (Fig. 2) is in line with the very recent findings obtained in *C. elegans*, which showed that the same mutation in EEL-1 (HUWE1 homologue) does not rescue GABE-ergic presynaptic transmission to the same extent as does the WT EEL-1²². In addition to Pol λ , HUWE1 p.R4187C could catalyze hyper-selfubiquitination that causes reduced HUWE1 protein levels, as observed in Fig. 1.

Pol λ was previously shown to play an important role in counteracting mutagenesis caused by the oxidative DNA base damage 8oxoG and reduction in its protein levels is known to cause hypersensitivity to oxidative stress^{13,28–31}. The hypersensitivity is thought to result from increased dATP misincorporation opposite 8oxoG that can lead to futile 8oxoG repair cycles, a byproduct of which are toxic single strand breaks. In line with this, we show that HUWE1-promoted XLID cells with reduced Pol λ levels incorporate more dATP opposite 8oxoG and display hypersensitivity to oxidative stress (Figs 1 and 3). Contribution of altered DNA repair to onset of IDs has been suggested through identification of causative mutations in several DNA repair genes^{16,17}. Besides increase in the mutation frequency and altered DNA repair, the hypersensitivity to oxidative stress might be particularly relevant for the onset of HUWE1-promoted XLID, as enhanced oxidative stress and insufficient antioxidant defense were suggested to play important pathophysiological role in XLID^{24,25}.

Given the high oxygen metabolism in the brain, the observed hypersensitivity to oxidative stress and the increased mutation frequency potentially contribute to an altered neuronal development in HUWE1-promoted XLID. This could be particularly relevant in cortical progenitor regions, where we show, by using cerebral organoids, that human HUWE1 localizes in pVim positive mitotic radial glia cells (Fig. 5). The observed localization further supports a conserved role of HUWE1 in neurodevelopment, as previously suggested by *HUWE1*-knockout mice studies^{18,20,21}. Loss of HUWE1 in the mouse brain caused an enlarged NSC compartment followed by disorganization of the cortical layers, revealing a crucial function of HUWE1 in triggering the maturation of neuronal progenitors residing in the cortical germinal layers. Further HUWE1 inactivation in mouse radial glia and cerebellar granule neuron precursors indicated an important function of HUWE1 in synchronization of neuronal and glial differentiation³⁷. Besides developing cerebral organoids from hiPSCs harboring HUWE1 WT we also attempted to develop cerebral organoids from HUWE1 p.R4187C hiPSCs. However, selection of HUWE1 p.R4187C containing hiPSCs proved to be inefficient (data not shown). Since HUWE1 is known to control NSC activity²⁰, it is possible that XLID-specific HUWE1 mutations would affect stem cell properties, which would hamper the selection of hiPSCs with mutated HUWE1. Follow up study addressing this is ongoing.

Overall, in this study we for the first time provide evidence that XLID-causing HUWE1 mutation leads to changed catalytic activity and results in alterations of essential cellular processes, such as maintenance of genome stability and response to oxidative stress, which could be relevant in cortical progenitor zones of human brain, as suggested by HUWE1 localization. By elucidating processes altered in HUWE1 p.R4187C XLID we provide first insights into molecular basis of this complex neurodevelopmental condition.

Methods

Cell culture. XLID individual LCLs were published previously⁵, while the healthy individual LCL (AG09387) was obtained from the Coriell Cell Repository (Coriell Institute for Medical Research, USA). LCLs were maintained in RPMI 1640 (Life Technologies) with 15% FCS (Life Technologies), 1% penicillin/streptomycin (Life Technologies), under 5% CO₂ atmosphere at 37°C. Human induced pluripotent stem cells (hiPSCs) ATCC-DYS0100 were obtained from ATCC (Manassas, USA) and were grown in mTeSR1 medium (STEMCELL Technologies) on CellMatrix Basement Membrane Gel coated dishes (ATCC), under 5% CO₂ atmosphere at 37°C.

Whole cell extracts. Lymphoblastoid cells growing in suspension were collected and washed twice with ice cold PBS, followed by flash freezing of the cell pellet in liquid N₂. Subsequently, the thawed cells were resuspended in one packed cell volume (PCV) of lysis buffer I (10 mM Tris-HCl pH 7.8, 200 mM KCl, 1 mM NEM, 0.1 mM MG-132, 1 μ M PMSE, 2 μ M leupeptin, 3 μ M bestatin, 1.5 μ M pepstatin) and two PCV of lysis buffer II (10 mM Tris-HCl pH 7.8, 600 mM KCl, 2 mM EDTA, 40% glycerol, 0.2% NP-40, 1 mM NEM, 0.1 mM MG-132, 1 μ M PMSE, 2 μ M leupeptin, 3 μ M bestatin, 1.5 μ M pepstatin). The samples were further rotated for 30 minutes at 4°C, sonicated and centrifuged. The supernatants representing WCEs were either flash frozen in liquid N₂ and stored at –80°C or used for analysis directly.

Immunoblot analysis. Whole cell extracts were either separated on a 7% Tris-Acetate polyacrylamide (PA) gel (HUWE1, BRCA1) or on a 10% Tris-Glycine PA gel and transferred to an Immobilon-FL membrane (Millipore) for subsequent immunoblotting. Primary antibodies were detected using infrared (IR) Dye-conjugated secondary antibodies (Rockland). The signal was visualized using direct IR fluorescence via

to electrophoresis in fresh alkaline solution for 20 min at 0.3 A. Finally, the slides were washed twice in ddH₂O, once in 70% ethanol and then left to air-dry. To visualize the DNA, the slides were stained with SYBR[®] Green I (Sigma-Aldrich) (in TE pH 8) for 15 min at 4 °C and washed twice for 10 min with ddH₂O. The dried slides were analyzed using the Comet Assay IV (Perceptive Instruments) system.

shRNA knockdown. Wild-type (WT) LCLs were lentivirally transduced with plasmids carrying the non-specific control shRNA (pGIPZ-Ns, Open Biosystems) or the Mule-targeting shRNA (GIPZ Human HUWE1 shRNA, Clone-ID V3LHS_353153, TCCTCTGTACCAACAACCT, Open Biosystems). Stable clones were subsequently selected with puromycin (1 µg/ml), while the selection-efficiency was monitored by the percentage of GFP-positive cells.

USP7 inhibitor treatment. Cells were treated with 8 µM of the USP7 inhibitor p5091 (Selleckchem) for 24 h before they were further used for a KBrO₃-viability assay or cell pellets were collected for WCE preparation and subsequent immunoblotting.

Cerebral organoids. hiPSCs have been differentiated to cerebellar organoids following protocol published by Lancaster and Knoblich⁴⁰. Briefly, feeder-independent hiPSCs were dissociated and allowed to reaggregate to form embryonic bodies, which were then subjected to neural induction in minimal medium allowing neuroectoderm formation. The neuroectodermal tissue was next transferred to Matrigel and upon outgrowth of neuroepithelial buds transferred to spinning bioreactor. 35-days after the initiation of differentiation cerebral organoids were collected and prepared for cryosectioning.

Immunofluorescence analysis. The 18-µm thick cryosections were immunostained following previously described procedure⁴¹. Briefly, upon drying sections were incubated in the blocking solution (PBS + 0.25% Triton + 10% goat serum) for 1 h at RT. Next primary antibody diluted in PBS + 0.25% Triton + 10% goat serum was added and sections incubated over night at 4 °C. After four washes with washing buffer (PBS + 0.25% Triton), secondary antibody diluted in PBS + 0.25% Triton was added and slides incubated for 2 h at room temperature. Slides were next washed four times with washing buffer, followed by two short washes with ddH₂O. Primary antibodies: phosphorylated Vimentin (Ser55) (D076-3S, MBL International), TUJ1 (MMS-435P, Covance) and HUWE1 (A300-486A, Bethyl Laboratories). Secondary antibodies: Goat anti-Rabbit IgG (H + L) Secondary Antibody, Alexa Fluor[®] 568 conjugate (A-11011, Thermo Fischer) and Goat anti-Mouse IgG (H + L) Secondary Antibody, Alexa Fluor[®] 488 conjugate (A-11029, Thermo Fischer). Microscopy was carried out using a Leica SP8 confocal microscope equipped with ×40 oil immersion lens, using Huygens software.

Statistical analysis. Differences in the endogenous mutation frequency, protein and mRNA levels, dNTP incorporation and the cell viability upon exposure to damaging agents were assessed using unpaired Student t-test in Prism 5.

Acknowledgements

This work has been partially supported by the Swiss National Science Foundation Grants to M.Bo., S.P. and M.A. (MD-PhD fellowship and Grant 150690); the Joint Research Committee between St. Olavs Hospital and Faculty of Medicine and Health Science, (NTNU) to R.A. and B.v.L.; the University of Zurich to M.Bo., C.G., E.M., M.A. and B.v.L. Medical Research Council and Cancer Research UK to G.D. and Norwegian Research Council to V.P. and M.Bj. We thank J.L. Parsons for purifying recombinant HUWE1; U. Hübscher and A. Aguzzi for critically reading the manuscript and the suggestions. Present address of G.F. Department of Clinical Biology, Jessa Hospital, 3500 Hasselt, Belgium; of E.M. Institute of Pharmacology and Toxicology, University of Zurich, 8057 Zürich, Switzerland.

Author Contributions

B.v.L. and G.L.D. had the original idea. B.v.L. supervised the project, interpreted the experiments and wrote the manuscript. M.Bo. performed the experiments and generated figures. R.A. contributed to the immunoblot analysis and the development of cerebral organoids. C.G. performed DNA polymerase assays. V.P. and M.Bj. contributed to the immunofluorescence analysis of cerebral organoids. E.M., S.P., L.R., G.F., M.A., P.H.B. and G.L.D. contributed reagents and structural and microscopy analyses. All authors reviewed the manuscript.
