Dynamic crystals with directional deformations in response to external stimuli through molecular reconfiguration, are observed predominantly in certain organic crystals and metal complexes. Low-dimensional hybrid halides, resemble these materials due to the presence of strong hydrogen bonds between bulky organic moieties and inorganic units, whereas their dynamic behavior remains largely unexplored. Here we show that a one-dimensional hybrid halide $(MV)BiBr_5$ (MV = methylviologen) undergoes an isosymmetric phase transition at hydrostatic pressure of 0.20 GPa, accompanied by a remarkable length expansion of 20–30% and red to dark yellow color change. Unexpectedly, the backward transition can be fully reversed by mechanical stimulation rather than decompression. In the high-pressure phase, the coexistence of strong Bi^{3+} lone pair stereochemical activity and large reorientations of the planar MV^{2+} cations, together with the newly formed CH···Br hydrogen interactions, are the structural features that facilitate microscopic changes and stabilize the metastable high-pressure phase at ambient conditions.

Dynamic crystals are a family of crystalline compounds that exhibit a mechanical response when subjected to external stimuli, demonstrating remarkable mechanical motion (for example, bending, jumping, curling, deformation, and rotation) due to the amplification of microscopic perturbation during molecular reconfiguration[1,2]. These intriguing properties allow this type of material to have potential applications in light-weight actuators, sensors, and flexible optoelectronic devices[3,4]. Previous studies have shown that the dynamic behavior typically correlates with rapid martensitic transitions, facilitated by the cooperative rearrangement of the molecular packing[5]. Most dynamic organic crystals and metal complexes undergo such a type of solid single-crystal-to-single-crystal (SC-to-SC) transitions that

are reversibly deformed. The original and transformed phases of the martensitic transition exhibit close orientation correlation and similar molecular packing within their crystal structures[6–11]. In addition, another SC-to-SC transition based on the nucleation and growth mechanism has also been reported. In the transformed phase, the structure has been reconstructed and thereby shows a large structural dissimilarity compared to the original phase. The cocrystal 7,7,8,8-tetracyanoquinodimethane-p-bis(8-hydroxyquinolinato) copper(II) (CuQ2-TCNQ) serves as a representative example of this type. It shows a 100% increase in single crystal length from form II to form I under mechanical stimulation, demonstrating a slow transition rate attributed to the cooperative movement of the stacked molecular sheets[12].

Most of these examples demonstrate reversible SC-to-SC phase transitions with shape and color modifications induced by light, temperature, pressure or organic vapor[13–16], however, mechanical-stimulation-triggered phase transformations are generally irreversible and the reversed phase changes are rarely reported[12,17,18].

The organic-inorganic hybrid metal halides, which are analogous to molecular crystals due to strong hydrogen bonds between bulky organic parts and inorganic units, typically exhibit reversible SC-to-SC phase transitions and tunable optical properties under variations of temperature and pressure[19–25]. If the metal centers were occupied by stereochemically active ns^2 lone pairs on the M^{2+} or M^{3+} cations, dynamic or static distortion of the local octahedral geometry appeared, which could give rise to distinctive lattice distortions, ferroelectricity, nonlinear optical and emission properties[26–30]. In contrast to dynamic crystals, concurrent dimension and color changes in these materials during the phase transitions are very rare. To date, there is only one example of a two-dimensional (2D) halide $(C_{12}H_{25}NH_3)_2PbI_4$ has been identified, exhibiting reversible size and color changes upon heating[31]. Pressure as an efficient tool, could effectively modulate the structural lattice and hydrogen bonding as well as the electronic structures of hybrid halides, resulting in reversible phase changes in most of cases[32,33]. However, investigations of the mechano-responsive (application of external stress) materials with fascinating dynamic properties in low-dimensional hybrid halides are still rare and unexplored.

Previous studies on the low-dimensional metal halides have shown that pressure can enhance the interactions between the small simple organic cations and the inorganic frameworks, shorten the B-X bond lengths, and consequently tune the optical properties[20]. In contrast to the external pressure, the influence of the steric effect of the small size cations on the structural stability can be negligible. However, the incorporation of large-size organic cations into such a low-dimensional system allows for a dramatic increase in steric hindrance in a confined space, which can easily lead to the distortions of inorganic components (for example, phase transition) when the external temperature and pressure change slightly. In this work, we present a pressure-induced irreversible SC-to-SC transition accompanied by drastic crystal shape and color changes and reversion upon mechanical stimulation in the one-dimensional (1D) hybrid halide $MVBiBr_5$ (MV = methylviologen), with the length of ~10 Å for the planar MV^{2+} cation. In the high-pressure phase, the stereochemical activity of the Bi^{3+} lone pair is activated, half of the planar MV^{2+} cations rotate by *ca.* 90° relative to the *ab* plane and subsequently generate new CH···Br hydrogen bonds, which are probably responsible for the considerable shape change and stabilization of the metastable high-pressure phase under ambient conditions. Remarkably, the transformed phase can revert to the original phase upon mechanical stimulation, as confirmed by single crystal X-ray diffraction, UV-vis absorption spectroscopy, and photoluminescence measurements. The pronounced shape and color alternations of the single crystal during the phase changes can be clearly visualized. Density functional theory (DFT) calculations reveal that the density of states near the Fermi level are similar in both phases, with the C-2p and N-2p states of the organic cation MV^{2+} and the Br-4p state dominated predominantly, which differs largely from that of conventional hybrid halide perovskites.

Results and discussion

The dark red single crystals of $(MV)BiBr_5$ were synthesized by the hydrothermal method at 423 K from the mixture of $BiBr_3$, 4,4′-bipyridine, and concentrated HBr in methanol as described previously[34,35]. At ambient conditions, $(MV)BiBr_5$ crystallizes in the monoclinic $P2_1/c$ space group with lattice parameters $a = 5.8578(2)$ Å, $b = 16.2786(5)$ Å, $c = 10.3856(3)$ Å and $\beta = 100.654(3)°$ ($Z = 2$, referred to as phase β). Upon cooling, phase β undergoes a paraelectric-to-ferroelectric phase transition to the polar phase α (space group $P2_1$) at 243 K, where the

Bi^{3+} lone pair becomes stereochemically activated, leading to an increase in the band gap[34]. Both phases have comparable lattice parameters, with only the length of the *c* axis contracts by 0.4% after β-α transition. The crystal structures of the phases α and β consist of the one-dimensional (1D) $BiBr_5$ chains separated by the planar MV^{2+} cations within the *bc* plane (Fig. 1a, b). The CH···Br hydrogen bonding motif remained almost the same in both phases, with the hydrogen atoms from the aromatic ring and the methyl group interacting with the Br atoms of the 1D corner-sharing $BiBr_6$ octahedra propagating along the *a* axis. Hence, based on the crystal habit and the Bravais-Friedel-Donnay-Harker (BFDH) morphology calculations, the crystallographic *a* axis should be parallel to the long direction of the rod-like single crystal (Figs. 2 and 3).

With increasing the pressure, we observed that the β phase stabilizes in a narrow pressure range at room temperature and it transforms to the γ phase as the pressure approaches 0.29 GPa. During the transformation to phase γ, the rod-shaped single crystals of phase β expand largely and visibly along the *a* axis whereas contract across their width, and the color concurrently changes from red to dark yellow (Fig. 3 and Supplementary Fig. 1). Due to the uncertainty of the pressure in the diamond anvil cell (DAC) chamber (0.03−0.05 GPa), the sample can be easily over-compressed at a high compressibility rate (for example, about 4.0−6.0 GPa/h) and the β phase transforms directly into the γ phase in most cases (Supplementary Movies 1 and 2). However, the limited space in the DAC chamber (~0.03 cm²) makes measuring the actuation force during the phase transformation under pressure challenging. Nevertheless, we clearly observed that the force generated during the phase transition could push a small metal piece to the chamber wall (Supplementary Movie 3). It is well-known that the compression rate plays a crucial role in the kinetic effects of pressure-induced phase transformations of the solids in the P-T phase diagrams[36,37]. Therefore, we attempted to load several single crystals of different dimensions into DAC chambers and compressed them at very slow rate (for example, about 0.2 GPa/h). Consequently, we observed the coexistence of phases β and γ at ~0.20 GPa with a noticeable color difference, and the phase transition process lasted for over 12 h (Fig. 3b, Supplementary Fig. 1d and Supplementary Movie 4). This observation together with the large alternations in the packing arrangements of the MV^{2+} cations, reveals that the β-γ phase transition is not of the martensitic type but can be classified as the nucleation and growth mechanism[38,39]. Moreover, we found that the length of all ten crystals was significantly elongated in the range of 20−30% along the *a* axis after the completion of the β-γ transition (Supplementary Fig. 1 and Supplementary Table 1). This magnitude is almost four times larger than that of the ~6% length elongation in the 2D halide $(C_{12}H_{25}NH_3)_2PbI_4$ during the thermally induced phase transition[31]. As can be inferred from previous high pressure studies, most crystalline materials tend to shrink in length during phase transitions (positive compressibility). However, there are few additional examples where this dynamic behavior has been noted[15,40,41], making $(MV)BiBr_5$ a very rare example that shows a large expansion of its length during a phase transition.

From the high-pressure single crystal X-ray diffraction (SXRD) measurements at room temperature, the γ phase is determined to have the same space group $P2_1/c$ as the β phase, but with expansions of all the lattice parameters a, b and c (at 0.29 GPa, $Z = 4$, $a = 6.0975(6)$ Å, $b = 17.292(2)$ Å, $c = 17.8464(18)$ Å and $\beta = 97.748(7)°$), resulting in a significantly different crystal structure compared to the β phase (Fig. 1). The centrosymmetric nature of phase γ was also verified by the second harmonic generation (SHG) measurements, which showed no SHG signal over the 300−1200 nm range (Supplementary Fig. 2). Moreover, synchrotron powder X-ray diffraction data were also collected up to 10.54 GPa at room temperature to investigate the phase stability of the sample (Supplementary Figs. 3 and 4). A pronounced volume collapse of ~2.8% for SXRD (~3.3% for PXRD) appears during the

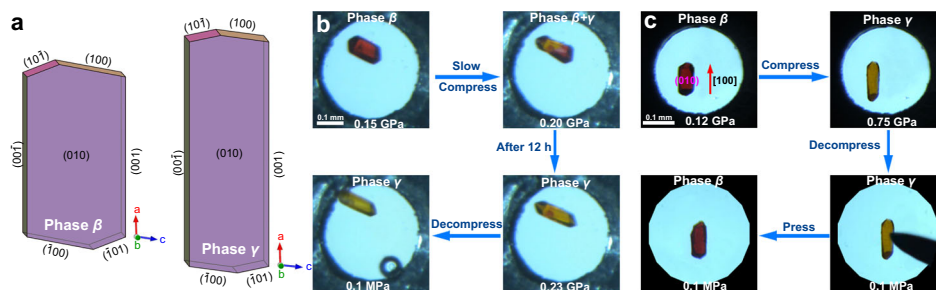

Fig. 3 | Changes in dimensions and color of (MV)BiBr₅ single crystals under external stress. a The predicted single crystal morphologies of phases β and γ based on BFDH model. **b** A single crystal was slowly compressed from 0.15 to 0.20 GPa (~0.2 GPa/h) and the coexistence of phase β to γ was observed. The phase β was completely transformed to γ over ~12 h and this phase was maintained after the pressure release to ambient pressure (see air bubbles). **c** A single crystal was compressed from 0.12 GPa (β phase) to 0.75 GPa (γ phase) in the DAC chamber and depressurized to 0.1 MPa. The γ phase reverts back to the β phase after mechanical stimulation (poking with a needle). The scale bars (white bars) are displayed in both **b** and **c** panels.

β-γ transition, which is typical characteristic of a first-order phase transition. At ~3.25 GPa, phase γ transforms to γ' without discontinuous changes in lattice parameters *a*, *b* and *c*, but the β angle starts to decrease under compression in phase γ' region (Fig. 2a and Supplementary Fig. 5). We attempted to use the γ phase structure model to refine the diffraction data of the γ' phase but were unsuccessful. Finally, the γ' phase is determined to be the $P2_1/n$ space group, and the γ-γ' transition can be considered as a second-order phase transition with subtle changes in the lattice parameters (Fig. 2). The γ' phase was observed to survive at least up to 10.54 GPa, as evidenced by the high-pressure PXRD measurements (Supplementary Fig. 3). In phase γ, the lattice parameters exhibit anisotropic compression, with the *a*-axis identified as the softest axis, which is primarily attributed to the presence of the highly compressible 1D BiBr₅ chains (Supplementary Fig. 6). For the SXRD measurements, the magnitude of the strain tensor β_1 is 22.6(12) TPa⁻¹, which is inclined by 17.8° to the *a* axis, and it is 1.3 times of that along the *b* axis (where β_b = 17.4(13) TPa⁻¹). The weakest compressibility is approximately along the *c* axis (inclined by 20.3°), with compressibility coefficient β_3 of 10.3(16) TPa⁻¹, which is half of that of β_1. Fitting the unit-cell volume of phase γ to the third Birch-Murnaghan equation of state yields a zero-pressure bulk modulus B_0 of 8.5(7) GPa and pressure derivative *B'* of 16(2). These magnitudes are comparable to those obtained from PXRD data (B_0 = 13(1) GPa and *B'* = 10(2)), as well as those of typical organic solids, but smaller than those of the low-dimensional halides[19,42,43].

In order to gain insight into the elastic properties of the γ phase, we employed the DFT method to calculate the full elastic constants. For the $P2_1/c$ monoclinic system, there are 13 independent elastic constants and the corresponding linear compressibility (β), bulk modulus (*B*), Young's modulus (*E*), shear modulus (*G*) and Poisson's ratio (*v*) are presented in Supplementary Tables 2 and 3, respectively. The maximum and minimum values of the elastic constants were obtained to verify the directional contribution using the ELATE software[44]. Due to the distinctive structural characteristics, the sample exhibits pronounced anisotropy in its elastic properties. As shown in Supplementary Fig. 8a, the calculated minimum and maximum magnitudes of linear compressibility are 18.04 TPa⁻¹ and 33.24 TPa⁻¹, respectively, and their directions are approximately along the [10$\bar{2}$] (inclined by 26.5° to the *c* axis) and [201] (inclined by 26.5° to the *a* axis). These values are in good agreement with the experimental observations (Supplementary Fig. 6). Moreover, the calculated bulk modulus *B* of the γ phase was found to be 12.80 GPa, which is reasonably close to the experimental values of 8.5(7) GPa (SXRD data) and 13(1) GPa (PXRD data). In addition, significant anisotropy is also found in *E*, *G* and *v*. For more detailed discussions, please refer to Supplemental Note 1.

Unlike conventional hybrid halides, which commonly exhibit elastic behavior under external temperature and pressure (that is,

reversible SC-to-SC phase transition with imperceptible shape changes)[19,45–47], the (MV)BiBr₅ crystal shows a very intriguing dynamic behavior. Unexpectedly, the transformed single crystal could not return to its original shape and color after the pressure was released to ambient pressure, revealing the irreversible character of the sample (Fig. 3, Supplementary Fig. 3, and Supplementary Video 2). Regardless of whether the pressure reached was in the γ or γ' (>3.25 GPa) phase region, all the recovered single crystals were conclusively identified as the γ phase by both SXRD and PXRD measurements (Supplementary Fig. 3 and Supplementary Table 4). Interestingly, when the (010) plane of the γ phase single crystal was pricked with a needle at room temperature, the single crystal alters its shape and color, and immediately transformed back to the β phase and its original shape, indicating that the γ phase is the metastable form at ambient conditions (Fig. 3c and Supplementary Table 5). We calculated the energy difference between phase β and phase γ to be 2.60 kJ/mol at ambient pressure, a value comparable to that observed in the most molecular crystals, for example, glycine[48,49]. The calculations suggest that the γ phase is a metastable phase at ambient conditions, whereas the β phase is the thermodynamically favored form. In order to gain insight into the irreversible γ-to-β phase transition mechanism, we propose a potential transition pathway with seven intermediate states generated by using interpolation method between γ and β phases. The proposed path gives rise to an activation energy barrier of ~290 meV/atom, which is most likely attributed to the large size of MV²⁺ cations and strong CH···Br hydrogen interactions within the lattice (for specific discussions, please refer to Supplementary Fig. 7 and Supplementary Note 2). When the local stress on the (010) face of phase γ is applied, β phase nuclei are initially produced and they diffuse across the entire crystal body, subsequently rearranging to the β phase through the reorientations of large MV²⁺ cations, which initiates the irreversible γ-β phase transition. Consequently, the distinct changes in color and dimensions are observed during the phase transformation (Fig. 3c). Previous studies on mechanical-stimulation-triggered SC-to-SC phase transitions are mainly on molecular crystals and metal complexes, with limited explorations in the hybrid halides. Typically, these phase changes result in the concomitant considerable shape and emission color modifications, as exemplified by phenomena like the "molecular domino" observed in arylgold(I) isocyanide complexes[12,17,50,51]. Therefore, (MV)BiBr₅ represents the extremely rare example of a pressure-induced irreversible SC-to-SC transformation and mechanical-stimulation-driven backward transition in 1D hybrid halides.

To understand the origin of the remarkable alternations in crystal dimensions during the β to γ transition, we determined the crystal structures before and after the transformation using high-pressure SXRD. In phase β, there is one type of MV²⁺ cation in the asymmetric unit (group A), whereas in phase γ there are two (group A and B). The

packing orientations of the planar MV^{2+} cations can be described by the dihedral angles φ_1 and φ_2 relative to the *ab* plane, respectively. The dihedral angle φ_1 in phase β is 39.6(2)° and it decreases to 37.4(6)° as the pressure increases from 0.1 MPa to 0.15 GPa (Supplementary Fig. 9). After the transition from phase β to γ, pronounced structural rearrangements are observed: MV group A undergoes a slight clockwise rotation, resulting in a smaller dihedral angle relative to the *ab* plane and still maintaining the "lying down" position, for example, φ_1 equals 28.9(6)° at 0.29 GPa. These small rotations of the MV group A can be explained by the ~7.1% expansion of the length of the *b* axis. However, an intriguing nearly 90° rotation of the MV group B is observed, and it transforms into a "standing up" position with a dihedral angle φ_2 of 89.5(4)°, contributing to a substantial ~72% expansion of the length of the *c* axis (Fig. 1d). The dihedral angles φ_1 and φ_2 decrease slightly under compression in the γ phase region and they maintain a similar trend in the γ' phase. In β phase, the adjacent Bi1···Bi1′ distance within the nearly regular corner-sharing BiBr$_6$ octahedra equals the lattice parameter *a* and it considerably elongates in phase γ due to activation of Bi^{3+} 6s^2 lone pair stereochemical activity. The extent of the BiBr$_6$ octahedral distortion can be qualified by the quadratic elongation ($\langle\lambda\rangle$) and bond angle variance (σ_θ^2), which are defined as follows:

$$\langle\lambda\rangle = \sum_{i=1}^{6}(l_i/l_0)^2/6 \qquad (1)$$

$$\sigma_\theta^2 = \sum_{i=1}^{12}(\theta_i - 90°)^2/11 \qquad (2)$$

where l_i is the Bi-Br bond length, l_0 is the average Bi-Br bond length, and θ_i is the Br-Bi-Br bond angle of neighboring bromides[52]. As shown in Fig. 2d, e, the octahedral distortion parameters $\langle\lambda\rangle$ and σ_θ^2 for the nearly regular BiBr$_6$ octahedra in phase β are (1.0002, 3.24) at ambient pressure. These values subsequently change to (1.0001, 3.78) as the pressure increases to 0.15 GPa, indicating enhanced Bi-Br covalent contacts. After the lone pair expression emerges in the polar phase α (0.1 MPa/243 K), the magnitudes of $\langle\lambda\rangle$ and σ_θ^2 are (1.0021, 6.18), indicating that the BiBr$_6$ octahedra become more distorted compared to phase β. In phase γ, the packing rearrangements of the MV cations result in the Bi-Br$_{axial}$ bonds having one short (Bi1-Br5) and one elongated (Bi1•••Br5′) along the *a* axis. At 0.29 GPa, the Bi1•••Br5′ bond length is 3.486(3) Å, exceeding the sum of $r_{Bi}{}^{3+} + r_{Br}{}^- = 2.99$ Å, which indicates the weak bonding. Upon compression, the Bi1•••Br5′ distance gradually reduces from 3.486(3) Å (at 0.29 GPa) to 3.219(5) Å (at 3.02 GPa), whereas the short Bi1-Br5 distance remains relatively unchanged (2.665(3) *vs.* 2.669(5) Å). The other four Bi-Br$_{equatorial}$ bond distances are comparable to those found in phase β and they are difficult to compress under pressure (Fig. 2c). Substantial changes in the $\langle\lambda\rangle$ and σ_θ^2 values are observed during the β-γ transition: they suddenly shift to (1.0081, 78.65) at 0.29 GPa, and then change monotonically with increasing the pressure to (1.0035, 121.12) at 3.02 GPa, and this trend is preserved even in the phase γ' region. The decrease in the $\langle\lambda\rangle$ is attributed to the reduction of Bi1-Br5′ distance under pressure as mentioned above, whereas the increase of σ_θ^2 value is caused by the large distortions of the BiBr$_6$ octahedra (Fig. 2). In contrast to phase β, the phase γ exhibits large magnitudes of octahedral distortion parameters, revealing that the BiBr$_6$ octahedra are more distorted and stronger lone pair stereochemical activity of the Bi^{3+} cations. It is clear to see that there are one short, one long and four intermediate Bi-Br bonds within the BiBr$_6$ octahedra, and the lone pair orbital should extend along the direction of Bi1•••Br5′ bond as notified from the Brown's model[53]. Moreover, the Bi-Br-Bi′ angle between the corner-sharing BiBr$_6$ octahedra along the *a* axis also undergoes abrupt changes during phase transition. For example, the Bi-Br-Bi′ bending angle is equal to 180° in phase β, and it suddenly drops to 164.79(8)° at 0.29 GPa after the phase β-γ transition.

Subsequently, it reduces monotonically throughout the entire phase γ region (by ~4.6° up to 3.02 GPa, see Fig. 2b). These observations emphasize the close correlations between the single crystal dimensions, MV^{2+} cations packing arrangements, Bi^{3+} 6s^2 lone pair expression and the BiBr$_6$ octahedral distortions.

The considerable reorientations of the MV^{2+} cations in phase γ lead to the formation of new hydrogen bonding patterns: the 1D BiBr$_6$ octahedra interacting with the CH donors from the aromatic ring and the methyl group of the MV^{2+} cations (group A and B, see Fig. 1c). From the released phase γ at ambient pressure, the CH•••Br distance ranges from 2.778 to 3.027 Å, which is comparable to that of phase β (2.792-3.017 Å). These observations imply that the strong CH•••Br hydrogen bonds could stabilize the crystal structure of phase γ at ambient pressure, thereby locking the metastable high-pressure structure and resulting in the irreversibility of the transition upon decompression[54]. However, when external stress is applied to the (010) face of the metastable phase γ, that is, the perpendicular direction where the CH•••Br hydrogen bonds dominate the MV^{2+} packing (1D BiBr$_5$ chains), it leads to hydrogen bond breaking and results in the alternations of the packing arrangements of the MV^{2+} cations (especially group B), thus driving the transformation of the metastable phase γ into the thermodynamically more stable phase β (Supplementary Fig. 10). Due to the more compacted structures in phase γ', more CH•••Br hydrogen bonds were formed, generating different hydrogen bonding patterns compared to phase γ (Fig. 1). The CH•••Br interactions in all three phases are gradually enhanced with increasing the pressure, and their evolutions under compression can also be clearly illustrated from the differences of Hirshfeld surfaces and two-dimensional (2D) fingerprint plots (Supplementary Figs. 11 and 12). In phase β, large red areas appear around the CH group within the aromatic ring, indicative of strong H•••Br bonding (Supplementary Fig. 12). In phase γ, there are two different MV groups within the structure and they show different Hirshfeld surfaces compared to phase β due to the newly formed CH•••Br hydrogen bonds (for example, C12H12C•••Br4, C10H10•••Br1). With increasing pressure, the distances of the H•••Br contacts shortened, characterized by the larger red areas on the Hirshfeld surface at 3.02 GPa. The relative contributions of the H•••Br contacts in MV group A and B are 39.7% and 41.3%, respectively, and they decrease to 36.6% and 37.1% as the pressure increases from 0.29 to 3.02 GPa within the phase γ region (Supplementary Fig. 13). The 2D fingerprint plots of phases β and γ contain one sharp spike corresponding to the strong CH•••Br hydrogen bond interactions and they are strongly enhanced under compression (see the shorter d_i and d_e distances in Supplementary Fig. 12).

During the β-γ transition of (MV)BiBr$_5$, the strong Bi^{3+} lone pair expression and rearrangements of MV^{2+} cations caused the crystal color to change abruptly from red to dark yellow, indicative of the electronic band gap alternations. The correlation between the lone pair stereochemical activity of Bi(III), Sn(II) and Pb(II) and the band gap has been observed in a several organic-inorganic hybrid halides[30,34,55,56]. To explore the variation of the band gap under pressure, in situ UV-vis absorption measurements were performed up to 9.78 GPa. At ambient pressure, the band gap of the β phase is 2.12 eV and its absorption edge exhibits a red shift under compression due to the shortening of the Bi-Br bond lengths (Fig. 2c). At transition pressure of 0.20 GPa, a sudden blueshift was observed with the energy band gap increases about 0.26 eV (Fig. 4a). With increasing pressure to 9.78 GPa within the γ' phase region, the single crystal color gradually darkens and changes to dark brown. Simultaneously, the band gap monotonically decreases to 2.17 eV, which is still larger than that of the β phase at ambient pressure (Fig. 4a, c). It is well known that the reduction of the B-X bond lengths generally reduces the band gap, whereas the distortion and tilting of the BX$_6$ octahedra play an opposite role in metal halides[57,58], such a rule also applies in the (MV)BiBr$_5$. Interestingly, the γ phase could be completely recovered upon pressure release to ambient pressure, with
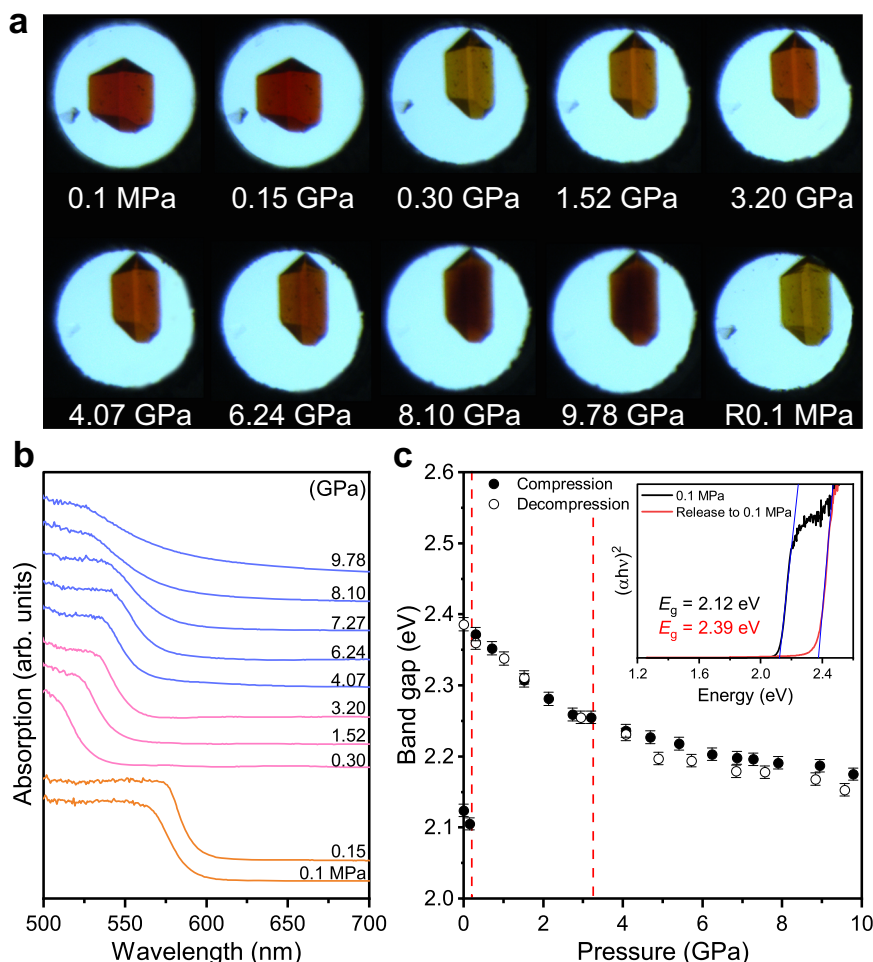

Fig. 4 | Optical properties of (MV)BiBr$_5$ at different pressures. a Optical images of a single crystal under pressure. The R0.1 MPa indicates the image when the pressure was completely released to the ambient pressure. **b** Evolution of the absorption spectra under compression. **c** Variations in the band gap of the sample under pressure. The inset shows the band gap of phase β (at 0.1 MPa) and phase γ released to ambient pressure at room temperature. Note that the error bars were obtained from the Tauc plot of the absorption spectra.

the band gap measured at 2.39 eV (Fig. 4a). Therefore, we used the pressure engineering strategy to synthesize a new phase of (MV)BiBr$_5$. As shown in Supplementary Fig. 14, the photoluminescence (PL) spectra exhibit a red shift of the PL peaks under compression, which is consistent with the observed changes in band gaps. The PL spectra of the sample exhibit red shift within the β phase region, a sudden blue shift appears during the β-γ phase transition. When the pressure is increased to 9.14 GPa, the PL spectra show an obvious redshift with a shift rate of 2.15 nm/GPa (Supplementary Fig. 14). It is noteworthy that the PL spectra could not be recovered after the pressure was released to ambient pressure, indicating an irreversible γ-β phase transformation. However, the crystal can return to its original spectra if mechanical stimulation is applied (Supplementary Fig. 14b). These observations are well consistent with the aforementioned XRD and absorption measurements.

The electronic structures of (MV)BiBr$_5$ at selected pressures were theoretically calculated by using both the PBE and HSE06 functionals. The results indicate that the β and γ phases are direct semiconductors, with both the valence band maximum (VBM) and conduction band minimum (CBM) located at the Y$_2$ point (Fig. 5). The ambient pressure band gaps obtained from the HSE06 (PBE) level for the β and γ phases are 1.89 (1.08) eV and 2.04 (1.18) eV, respectively. In contrast to the PBE method, the band gaps calculated at the HSE06 level give a better agreement with the experimental results of 2.12 eV (β phase) and 2.39 eV (γ phase), thereby validating the higher accuracy of the HSE06

functional. The band dispersions based on the HSE06 level are nearly identical to those obtained on the PBE level, with the exception that the conduction and valence bands are somewhat shifted away from the Fermi level due to the corrected gaps (see Supplementary Fig. 15). As shown in Fig. 5, the CBM in phase β at 0.1 MPa is primarily comprised of C-2p, Bi-6p, and N-2p states, whereas the main constituents in phase γ are C-2p and N-2p states. The VBM is mainly dominated by Br-4p state with a minor contribution from the Bi-6s state in phase β, whereas such small contribution disappears in phase γ due to the emergence of the Bi 6s^2 lone pair expression. This unique feature differs from that of conventional hybrid halide perovskites, in which the VBM is mainly composed of B-cation ns and halide np states and the CBM is predominantly contributed by the B-cation np state, with negligible contributions from the organic moieties[59,60]. In the γ phase, the Bi1•••Br5' bond lengths are gradually shortened and the CH•••Br hydrogen interactions are strongly enhanced under compression, which increases the orbital overlap between the Br-4p, C-2p and N-2p states, and thereby narrows the band gap (that is, 1.64 eV at 3.02 GPa for HSE06 calculations). Interestingly, we observe the gradual shift of the Bi-6p and Br-4p orbitals towards the Fermi level as the pressure is increased in phase γ (Fig. 5b–d), which is consistent with the large reduction in Bi1•••Br5' bond distances (Fig. 2c).

To visualize the lone pair electrons on the Bi atoms, the electron localization function (ELF) calculations of β and γ phases are presented in Supplementary Fig. 16. In the case of phase β at
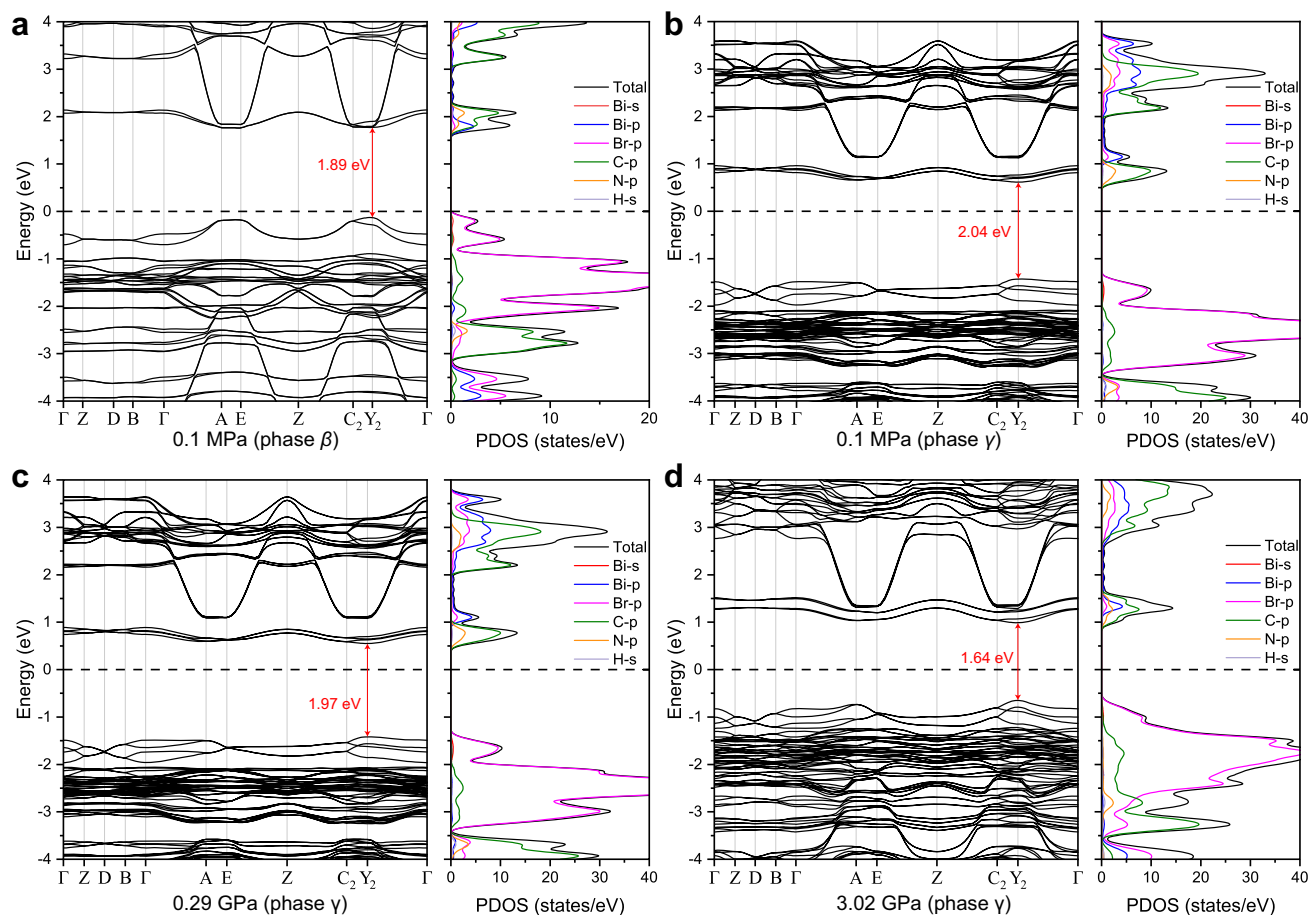

Fig. 5 | The electronic structures of (MV)BiBr$_5$ at selective pressures calculated by using HSE06 functional. a β phase at 0.1 MPa; **b**–**d** γ phase at 0.1 MPa, 0.29 GPa and 3.02 GPa. Note that the PDOS stands for projected density of states. The Fermi level is set to 0 eV.

0.1 MPa, we observe a strong covalency between Bi and Br atoms, indicating the absence of lone pair expression due to the short Bi-Br bond length. Inversely, a lobe-shaped ELF feature appears around Bi atom in phase γ, indicating that the orientations of the lone pair electrons should be toward the [100] direction (that is, along the 1D BiBr$_5$ chain). With increasing pressure, the lobe-like shape around the Bi atom becomes smaller, revealing the stereochemical activity of the Bi^{3+} lone pair electron is suppressed due to the shortened Bi1•••Br5′ distance (see Supplementary Fig. 16c). Moreover, in order to check whether the sudden increase of the Bi-Br bond distance in phase γ results in a change of Bi oxidation state under pressure, we performed a Bader charge analysis (Supplementary Table 6). The results show that the charges on the Bi1 atom in the phases β and γ are comparable at 0.1 MPa (3.629e vs 3.640e), and this magnitude remained almost the same as the pressure increases to 3.02 GPa (3.639e), revealing that the trivalent nature of the Bi1 atoms is maintained at high pressure. Additionally, the average charge on the Br atom becomes slightly less negative with increasing pressure in the phase γ region (−0.588e vs −0.568e).

In this work, we present the dynamic behavior of the 1D hybrid halide (MV)BiBr$_5$, which undergoes a pressure-induced irreversible SC-to-SC transition with a remarkable 20–30% elongation in length and a color change from red to dark yellow with an increase in band gap by 0.26 eV. Notably, the backward transition can be completely driven by mechanical stimulation rather than decompression. The combination of two types of SC-to-SC phase transitions enables the reversible structural and color alternations. Generally, hybrids of this kind are conventionally regarded as robust compounds, but the material studied here demonstrates excellent mechanical responsive feature. From the detailed single crystal structure analysis and electronic structures calculations, we find that the activation of the Bi^{3+} lone pair stereochemical activity leads to the elongation of the 1D BiBr$_5$ chains along the a axis and a slightly wider band gap. Meanwhile, half of the planar MV^{2+} cations undergo an almost 90° rotation relative to the ab plane together with the newly formed strong CH···Br hydrogen bonds are thus considered to play a significant role in the noticeable shape and color changes as observed. To the best of our knowledge, this is the extremely rare observation of a 1D hybrid halide that behaves similarly to dynamic organic crystals and metal complexes, providing new insights for the design of novel stimuli-responsive materials.

Methods

Synthesis of (MV)BiBr$_5$ single crystals

The (MV)BiBr$_5$ single crystals were synthesized using a traditional hydrothermal method as reported previously[34,35]. 0.5 mmol BiBr$_3$ (98%, Aladdin) and 0.5 mmol 4,4′-bipyridine (98%, Aladdin) were placed in the lining of a 25 mL hydrothermal reaction autoclave, then 2 mL 48% hydrobromic acid, and 3 mL methanol were added, stirred for -15 min and the autoclave was then sealed. The autoclave was heated to 423 K over 2 h, maintained at this temperature for 72 h, and then slowly cooled to room temperature at a rate of 5 K/h. Finally, red block (MV)BiBr$_5$ single crystals were finally obtained by rapid washing with ethanol.

Single crystal and powder X-ray diffraction measurements

The ambient pressure single crystal X-ray diffraction data of (MV)BiBr$_5$ were collected on the Rigaku XtaLAB Synergy-R diffractometer equipped with graphite monochromatic MoKα radiation (λ = 0.71073 Å). The

single crystal structure was solved by direct method using the SHELXS program[61], and refined by full-matrix least-squares optimization on F^2 using SHELXL program on OLEX2[62].

High-pressure single crystal X-ray diffraction (SXRD) data of (MV) $BiBr_5$ were collected on a Bruker D8 Venture diffractometer with Phonon II detector, fixed-chi goniometer and Incoatec IµS 3.0 AgKα microfocus source with Helios AgKα radiation (λ = 0.56086 Å). High-pressure X-ray data were collected by using eight different ω scans and an exposure time of 60 s for each frame. A single crystal with dimensions of $0.15 \times 0.12 \times 0.07$ mm^3 was loaded into a diamond anvil cell (DAC) chamber, neon gas was used as pressure transmitting medium (PTM). The diameter of the diamond anvil culet is 500 µm and the aperture opening angle is 80°. The stainless-steel foil was pre-indented to a thickness of ~100 µm and the hole was laser drilled to a diameter about 230 µm. The DAC was mounted on the motorized XYZ stage attached to the Omega platform. The pressure was calibrated using the ruby fluorescence method with an accuracy of 0.03-0.05 GPa before and after each X-ray data acquisition[63]. A total of 12 high-pressure points were measured, ranging from 0.15 GPa to 5.26 GPa at room temperature. Data collection, indexing and reduction were performed using the APEX3 software. Structure refinements were performed using SHELXL-97 software. The selected crystallographic details at variable pressures are listed in Table S2. In addition, the EoSFit7c software was used to perform the least-squares fitting of V(P) data using the third-order Birch-Murnaghan equation of states (EoS) for phase γ of (MV)BiBr$_5$[64].

High-pressure angle-dispersive powder X-ray (PXRD) measurements were collected on the BL04-MSPD beamline at the ALBA Synchrotron using a monochromatic beam wavelength λ = 0.4246 Å. The X-ray data were recorded on an SX165 Rayonix Mar charge-coupled device (CCD) detector. Silicone oil was employed as the pressure transmitting medium and a small piece of Au was used for the pressure calibration. A membrane system coupled with a symmetric DAC was used to control the pressure. The collected diffraction images were integrated using the *Dioptas* 0.5.1 software[65], and XRD patterns were fitted by the Le Bail fitting method using GSAS-EXPGUI package[66]. The single crystal structures of (MV)BiBr$_5$ were used as the starting models to carry out all the data refinements.

Compressibility measurements
In order to gain a comprehensive understanding of the phase transitions of (MV)BiBr$_5$, ten single crystals were compressed at different compressibility rates at room temperature. A double membrane system coupled with a symmetric DAC with a large culet size (diameter: 600 µm) is used for the continuous compression/decompression. The pressure is determined by the online ruby system and the videos (Supplementary Movies 1–4) were recorded simultaneously. In certain cases (particularly for the decompression paths), if the DAC chamber pressure fails to reach the ambient pressure when the membrane gas pressure is completely released, the screws of the symmetric DAC are manually loosened.

High-pressure UV-vis absorption spectroscopy
High pressure in situ UV-vis absorption measurements of (MV)BiBr$_5$ single crystal were performed in a home-built spectroscopy system using a deuterium-halogen lamp 2-in-1 light source in the range of 300-1200 nm. Silicone oil (10 cSt) was used as PTM. The direct band gap values are determined by extrapolating the linear part of the $(αhv)^2$ versus hv curve, where $α$ is the absorption coefficient, h is the Planck constant, and v is the frequency of the photon.

High-pressure photoluminescence spectroscopy
High-pressure in situ photoluminescence (PL) measurements of (MV) BiBr$_5$ were conducted in a home-built spectroscopy system using an Ocean Optics QE series spectrometer. Silicone oil (10 cSt) was used as the PTM. A 532 nm green laser was used as the PL excitation source.

Second harmonic generation measurements
Second harmonic generation (SHG) measurements were employed to confirm the presence of an inversion center in the crystal structure of (MV)BiBr$_5$. The measurements were conducted using a home-designed goLite Solution-NLO optical system. A pulsed fiber laser (Rainbow1064Pro, 1064 nm, 20 MHz, <15 ps) was used as the excitation light source. A 50× objective was used to focus the laser with a laser spot of 10 µm in diameter. A spectrometer (NVOA2S-EX) was used to collect the SHG signal. Silicone oil was used as the PTM. The system was validated using a small KH$_2$PO$_4$ (KDP) single crystal. The results show the absence of SHG signals in both ambient and high-pressure phases of (MV)BiBr$_5$ (Supplementary Fig. 2), revealing that the centrosymmetric nature of the high pressure phase, consistent with the space group $P2_1/c$ as determined by single crystal X-ray diffraction measurements.

Theoretical calculations
Density functional theory (DFT) calculations including density of states, band structure, elastic constants, electron localization functions (ELFs) as well as Bader charges of (MV)BiBr$_5$ at selective pressures were performed using the projector augmented wave (PAW) method[67,68], as implemented in the Vienna Ab initio Simulation Package (VASP)[69,70]. The PBE exchange-correlation functional[71], with a 400 eV plane-wave cutoff for both phases $β$ and $γ$ was adopted. In the structure optimizations, the $6 \times 2 \times 3$ and $5 \times 2 \times 2$ k-points were utilized for phases $β$ and $γ$, respectively, and the Hellmann-Feynman force acting on each atom is less than 0.01 eV/ Å. In electronic structures and energy calculations, a denser Monkhorst-Pack grid of $14 \times 5 \times 5$ and $15 \times 5 \times 8$ in the Brillouin zone was adopted for $β$ and $γ$ phases, respectively. Since the PBE functionals usually underestimate the band gap, the HSE06 hybrid functional was utilized to correct the band gap and dispersion. In order to clarify the irreversible phase transition mechanism from $γ$ to $β$ phase, the climbing-image nudged elastic band (CI-NEB) method was adopted to evaluate the kinetic barrier of the phase transition. Seven intermediate state configurations were generated by using the interpolation method in the CI-NEB calculations[72]. High-symmetry points of Γ, Z, D, B, A, E, C$_2$ and Y$_2$ in the Brillouin zones correspond to (0, 0, 0), (0, 0.5, 0), (0, 0.5, 0.5), (0, 0, 0.5), (−0.5, 0, 0.5), (−0.5, 0.5, 0.5), (−0.5, 0.5, 0), and (−0.5, 0, 0) points for phases $β$ and $γ$ for band structure calculations, respectively. The Bi 5d^{10}6s^{2}6p^3, Br 4s^{2}4p^5, C 2s^{2}2p^2, N 2s^{2}2p^3, and H 1s^1 were explicitly treated as valence electrons. All calculations were performed using the experimental unit-cell lattice parameters obtained from the SXRD measurements, while the atomic positions within the lattice were optimized.

Data availability
The data supporting the findings of this study are available within the main text and the Supplementary Information file. Source data are provided with this paper. Crystallographic data for structures reported in this paper have been deposited in the Cambridge Crystallographic Data Center under reference numbers CCDC 2324652 − 2324662. These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif. Supplementary information is available for this paper. Source data are provided with this paper.

Acknowledgements

Author contributions

W.C. conceived and supervised the study. D.Z. synthesized single crystal samples and conducted high-pressure absorption measurements, and analyzed the single crystal X-ray data; B.F., F.L., L.W., and H.Liu. collected and analyzed the high-pressure single-crystal X-ray diffraction data. W.H. recorded the videos and processed the data. H.Li. and L.Z. performed the theoretical calculations. D.Z. and W.H. prepared the figures for the manuscript. This paper was written with the contributions from D.Z., W.H., and W.C., and all other authors contributed to editing the manuscript thereafter.
