Abstract. The relationship between nuclear factor I/B (NFIB) and cancer attracts growing research interest. NFIB has diverse and specific roles in tumor progression and invasion. However, the potential effects and functions of this transcription factor in melanoma remain unclear. The present study sought to determine the distinguishing properties of NFIB in melanoma cells. Immunohistochemical examination of the tissues of 15 patients with melanoma indicated that the expression of NFIB was high in melanoma specimens, compared with the benign nevus and normal skin specimens. In addition, the relationship between high NFIB expression and low overall survival rate was assessed. Functional studies demonstrated that NFIB enhanced the malignancy of melanoma, including proliferation, migration and invasion. In addition, NFIB silencing in A375 and A875 cell lines inhibited the process of epithelial-mesenchymal transition (EMT), upregulated E-cadherin and zona occludens-1, but suppressed N-cadherin and vimentin expression. These findings may suggest a new function of NFIB in promoting the migration and invasion of melanoma cells. Therefore, the present study further evaluated the association between NFIB and zinc finger protein E-box binding homeobox-1 (ZEB1) in melanoma. Mechanistic experiments revealed that NFIB exerted its roles during EMT by regulating ZEB1. Overall, the present data indicates that NFIB promotes the malignancy of melanoma, particularly EMT, by modulating the ZEB1 axis, such as ZEB2, ATM and CHK1, which may represent a potential molecular therapeutic target in melanoma.

Introduction

Malignant melanoma, which arises from melanocytes, is lethal and common in the global population, ranking 5th for the incidence of malignant tumors in males, and 6th in females for mortality rate (1). Furthermore, its mortality seriously threatens human health and imparts a grave economic burden (2,3). Although surgical resection of malignant tissue is recognized as the most effective therapy in the early stages of melanoma, the 5-year survival rate in metastatic melanoma is only 15%, with patients experiencing a very poor prognosis (4,5). Furthermore, melanoma is characterized by high rates of recurrence with high mortality, often diagnosed in the last stages and resistant to current therapeutic approaches (6,7). Therefore, further studies are needed to identify novel biomarkers for malignant melanoma and to develop a deeper understanding of the mechanisms that lead to melanoma progression.

Epithelial-mesenchymal transition (EMT) is an indispensable biological process that is closely connected to embryogenesis and the first stage of wound healing (8). Recently, it has become widely acknowledged that the mechanism of EMT is more complex in melanoma. Indeed, abnormal activation of the EMT pathway alters the micro-environment by which epithelial tumor cells that initially undergo EMT are able to revert to epithelial phenotype by mesenchymal-epithelial transition at the distant site, therefore tumor cells penetrate the basement membrane and migrate (9). A variety of transcription factors act as molecular switches that directly regulate the occurrence of the EMT process in melanoma (10,11). Among these, zinc finger protein E-box binding homeobox (ZEB) proteins, especially ZEB1 and -2, participate in the initiation of EMT in melanoma by downregulating the expression in microphthalmia-associated transcription factor (MITF) (12).

Nuclear factor I (NFI) is a type of transcription factor family, which is widely found in mammals and also known as CCAAT box-binding transcription factor (CTF). This family is characterized by a highly conserved N-terminal DNA-binding region, and divided into four subtypes (A, B, C and X) based on the variable C-terminus region (13,14). NFIs are known to be involved in the regulation of DNA replication and gene expression and to promote cell proliferation and differentiation during the embryonic development (15-17).

Key words: melanoma, nuclear factor I/B, epithelial-mesenchymal transition, zinc finger protein E-Box binding homeobox 1, metastasis

In addition, NFIs are abnormally expressed in various tumors and has a complex and diverse function in some tumors (18). For instance, human NFI type-B (NFIB) serves a crucial role in different aspects of tumor development, acting as an oncogene or tumor suppressor in different types of tumor and participating in tumor-associated fusion gene formation (19-21). Previous studies on the role of NFIB in colorectal cancer (CRC) have indicated that NFIB triggers EMT of CRC cells through upregulation of SNAI1 expression (22). Moreover, NFIB seems to mediate the conversion between the two transcription factors, POU class 3 homeobox 2 and MITF, through the upregulation of enhancer of zeste homolog 2, which increases expression of MITF and decreases expression of BRN2, thus driving the invasive phenotype in the melanoma (23). However, few studies have been conducted on the specific mechanisms involved in melanoma metastasis based on NFIB. Thus, the present study investigated the impact of NFIB on EMT in A375 and A875 cell lines. Given that ZEB1 has two possible binding sites for the NFIB promoter (24), it was hypothesized that there was an association between ZEB1 and NFIB. The findings of this study may provide insight into the metastasis of malignant melanoma, with particular emphasis on EMT.

Materials and methods

Clinical specimens. To detect the expression of NFIB by immunohistochemistry (IHC), 15 melanoma samples, 15 benign nevus samples and 10 normal skin samples were collected between December 2017 and January 2018 from different patients. The total number of patients enrolled for the study was 40. Clinical samples of melanoma and nevus in this study were provided and pathologically diagnosed by the Department of Dermatology, Tongji Hospital affiliated with Huazhong University of Science and Technology, while normal skin samples were obtained from the Department of Urology, Tongji Hospital affiliated with Huazhong University of Science and Technology. These tissue specimens were fixed in 10% formalin at room temperature after resection. After 24 h of fixation, the samples were then embedded in paraffin for IHC. All the participants were newly diagnosed and had not received any comprehensive antitumor treatment before the surgical section. They were informed of their rights and signed an informed consent form. The present study was approved by the Ethics Review Committee at Tongji Hospital affiliated with Huazhong University of Science and Technology.

IHC analysis. The expressions of NFIB protein in the samples of melanoma, nevus and normal skin were detected by IHC. All three kinds of specimens were cut into uniform sections of 3- μ m thickness. The samples were treated with 10% polylysine, then fixed on glass slides using melted paraffin at 65°C for 5 min and baked in an oven at 65°C overnight. The next day, the prepared sections were hydrated by dewaxing with graded alcohol and xylene at room temperature. Thereafter, antigen retrieval was carried out using 600 ml 10 mM sodium citrate (pH 6.0) heated in a microwave oven at 100°C for 6-8 min and then cooled at room temperature. Several drops of hydrogen peroxide were then added for incubation at room temperature for 15 min to neutralize the excess oxygen radicals and reduce

the background. Then, a primary antibody specific for NFIB (cat. no. ab186738; 1:100 dilution; Abcam) was added to the sections at 4°C overnight, followed by incubation with a secondary antibody conjugated with streptavidin-HRP at room temperature for 30 min. A freshly prepared DAB coloring solution was used to enhance coloration with hematoxylin re-dyeing, 1% hydrochloric acid ethanol differentiation, trypan blue pan-blue and gradient alcohol dehydration. Subsequently, the relative intensity of NFIB expression was evaluated using Image-Pro Plus software (IPP version 6.0; Media Cybernetics, Inc.).

Bioinformatics analysis. The present study analyzed from TCGA website (<https://xenabrowser.net/heatmap/>) and the Oncomine Cancer Microarray database (<https://www.oncomine.org/resource/login.html>) to compare the expression levels of NFIB mRNA in 227 samples, including 92 melanoma, 85 benign nevus and 50 normal skin specimens. In each dataset, the median value of NFIB expression was used to divide the samples into an NFIB high-expression group and an NFIB low-expression group. The analysis was performed using GraphPad Prism 5.0 and log-rank tests (GraphPad Software, Inc.).

Cell lines and culture condition. The human melanoma cell lines A375, A875 and SK-MEL-1, and the normal HaCaT keratinocyte cell line were purchased from the China Center for Type Culture Collection. HaCaT cells were authenticated by STR. All cell lines were resuspended in Dulbecco's Modified Eagle Medium (DMEM; Gibco; Thermo Fisher Scientific, Inc.) supplemented with 10% fetal bovine serum (FBS; Gibco; Thermo Fisher Scientific, Inc.) and incubated at 37°C with 5% CO₂. The cell culture medium was replaced or the cells were sub-cultured, as appropriate, every 1-2 days.

Cell transfection. A375 and A875 cells were uniformly seeded into 6-well plates at 4x10⁵ cells/well and incubated overnight. The cells were resuspended in Opti-MEM (Thermo Fisher Scientific, Inc) then transfected with small interfering (si) RNA (si-NFIB, 5'-AGGAUACUCUGAAGAACUAUU-3'; Guangzhou RiboBio Co., Ltd.) to silence NFIB expression at 50 nM/well. The transfected cells were screened using puromycin (5.0 μ g/ml). The recombinant plasmid pcDNA.3.1-NFIB (Guangzhou RiboBio Co., Ltd.) was transfected into A375 and A875 cells to induce NFIB overexpression at 0.2 μ g/well. si-negative control (NC; 5'-TTCTCCGAACGTGTCACGTdT-3') and empty vectors were used as controls. Silencing and overexpression efficiency were examined by western blot and reverse transcription-quantitative PCR (RT-qPCR). After 10 days of lentivirus transfection or 72 h after siRNA transfection, western blot and RT-PCR analyses were used to detect the expression of target genes. Plasmids pcDNA-NFIB were transfected into 293T cells for luciferase reporter assays.

Establishment of an EMT model of melanoma cells. The A375 and A875 cells were uniformly seeded into a 6-well plate at a density of 4x10⁵ cells/well, and cultured to ~75% confluence. Cells were then treated with 5 ng/ml TGF- β 1. TGF- β 1 (PeproTech, Inc.) was used to stimulate EMT. Untreated cells were used as a control. A phase-contrast microscope (Model

CKX41; magnification, x100; Olympus Corporation) was used to examine cell morphological changes after 24 h.

RT-qPCR. Total RNA was extracted from cells 48 h following transfection using TRIzol[®] solution following the manufacturer's instructions (Thermo Fisher Scientific, Inc.). An ultraviolet spectrophotometer with a wavelength between 260 and 280 nm was used to measure the RNA concentration. Total RNA was reverse transcribed to cDNA with RT Master Mix (Takara Bio, Inc.) according to the manufacturer's instructions. RT-PCR was performed with SYBR Master Mix (Takara Bio, Inc.) using the StepOne-Plus system (Thermo Fisher Scientific, Inc.). RT-PCR was performed with 40 cycles under the following conditions: Denaturation at 95°C for 30 sec, annealing at 60°C for 1 min and extension at 95°C for 5 sec. Each experiment was conducted three times. The specific primer sequences for evaluating the NFIB expression in melanoma cell lines were as follows: i) NFIB forward, 5'-AAAAAGCATGAGAAGCGAATGTC-3'; ii) NFIB reverse, 5'-ACTCCTGGCGAATATCTT TGC-3'; iii) GAPDH forward, 5'-ACAACCTTTGGTATCG TGGAAGG-3'; and iv) GAPDH reverse, 5'-GCCATCACG CCACAGTTTC-3'. GAPDH served as an endogenous control to normalize NFIB expression in each sample. The relative expression of NFIB was calculated using the comparative Cq ($2^{-\Delta\Delta Cq}$) method (25).

Cell proliferation. The Cell Counting Kit-8 (CCK-8; Beijing Baisi Biological Technology Co., Ltd.) was used to evaluate the rate of cell proliferation. In brief, A375 and A875 cells were uniformly seeded into three 96-well plates at a density of 1×10^3 cells/well, in culture medium volume 100 μ l/well. 10 μ l CCK-8 solution was added into the media. The absorbance of cells was assessed at a fixed time every day, and the data were continuously detected by a microplate reader (Thermo Fisher Scientific, Inc.). The optical density of cells was measured at a 450 nm wavelength. The cells were incubated for 24, 48 and 72 h at 37°C with 5% CO₂.

Colony formation assay. Melanoma cells in the logarithmic growth period were seeded in a 6-well plate at a density of 5×10 cells/well containing DMEM medium with 10% FBS and incubated at 37°C in a humidified incubator with 5% CO₂. When the colonies were visible to the naked eye, the culture was stopped immediately and then fixed with 4% paraformaldehyde (Google Biotechnology Co., Ltd.) and stained by 0.1% crystal violet (Google Biotechnology Co., Ltd.). Finally, the number of colonies (>50 cells) were analyzed under an inverted microscope (Olympus Corporation), and the colony number and colony formation rates were calculated. Clone formation rate=(number of clones/number of inoculated cells) x100%.

Wound healing assay. To assess the effects of NFIB on cell migration, 5×10^4 A375 and A875 cells were seeded during the logarithmic growth period in the 6-well plate to ensure that the cells would reach 90-100% confluency the next day. Three parallel lines were drawn on the back of the 6-well plate with a marker pen, and a 100- μ l pipette tip was selected to draw a line on the bottom of the cell of the 6-well plate. After this, the cells were washed with sterile PBS repeatedly 3-5 times

to remove floating cell debris. The cells were then cultured in serum-free medium for 24 and 48 h. Migration between scratches was observed under an inverted microscope under x100 magnification and kept at the same position and time under the mark.

Cell migration and invasion assay. Migration and invasion were evaluated in 24-well Transwell chambers (Corning Inc.) in the presence or absence of Matrigel[™] ECM (Corning Inc.) coating. After transfection for 48 h, A375 (5×10^4 cells/chamber) and A875 (1×10^5 cells/chamber) cells resuspended in 200 μ l of serum-free DMEM medium were seeded into the upper chamber. The lower chamber received 600 μ l of DMEM medium mixed with 10% FBS. Then, the cells were incubated for an additional 24 h for migration assays or 48 h for invasion assays at 37°C with 5% CO₂. Finally, the cells in the upper chamber were wiped off with a cotton bud, and the penetrated cells underneath the chamber were fixed with 4% paraformaldehyde and stained with 0.1% crystal violet staining solution (both at room temperature for 30 min). The cells were counted in five randomly selected fields for each membrane under an inverted microscope and photographed at x100 magnification.

Western blot analysis. Total protein was extracted using RIPA buffer (Thermo Fisher Scientific, Inc.) supplemented with protease inhibitor cocktail and 1% PMSF (Roche Diagnostics). The protein was quantified using a BCA Protein Assay Reagent kit (Thermo Fisher Scientific, Inc.) and were collected and mixed with loading buffer. Equal amounts of protein (40 μ g) from each sample were separated by 10% SDS-PAGE and transferred to PVDF membranes (EMD Millipore). The membranes were blocked in 5% milk in TBST buffer for 2 h at room temperature, then incubated with primary antibodies at the recommended dilution overnight at 4°C. After binding with secondary antibody conjugated HRP at room temperature for 1 h, Image J (National Institutes of Health) was used to measure the band density. GAPDH acted as an internal reference, and each sample was analyzed three times. NFIB (1:1,000; cat. no. ab80835) and GAPDH (1:1,000; cat. no. ab9485) antibodies were purchased from Abcam. Vimentin (1:1,000; cat. no. 10366-1-AP) were purchased from ProteinTech Group, Inc. E-cadherin (1:1,000; cat. no. sc-71007) and N-cadherin (1:1,000; cat. no. sc-71002) were purchased from Santa Cruz Biotechnology, Inc. Secondary horseradish peroxidase-goat anti-rabbit antibodies (1:1,000; cat. no. 10285-1-AP) were purchased from ProteinTech Group, Inc.

Statistical analysis. All data are presented as the mean \pm standard deviations (SD) from three independent experiments. All statistical analyses were performed using GraphPad Prism (version 6.0; GraphPad Software, Inc.). Unpaired Student's t-test was employed to compare the difference between two groups. One-way ANOVA followed by the Least Significant Difference was used for multigroup comparisons. The log-rank test and Kaplan-Meier survival curves were used to analyze the association between NFIB expression and overall survival. Statistical analyses were performed using GraphPad Prism 5.0 (GraphPad Software, Inc.). P<0.05 was considered to indicate a statistically significant difference.

Figure 1. NFIB is highly expressed in human malignant melanoma tissues and associated with poor prognosis. (A) Immunohistochemical staining of NFIB in melanoma tissues, paired with benign nevus and normal skin. $P < 0.001$, one-way ANOVA test. Kaplan-Meier survival analysis and log-rank test were used to evaluate the effect of NFIB expression on overall survival. (D) NFIB protein expression in the A375, A875 and SK-MEL1 human melanoma cell lines and the normal human HaCaT keratinocytes. NFIB, nuclear factor I/B.

Results

NFIB is relatively high in human malignant melanoma and associated with poor prognosis. The expression and molecular mechanism of NFIB have not been clearly reported in melanoma previously. Initially, the present study analyzed the localization of NFIB in clinical samples. NFIB expression levels were examined by IHC in 15 malignant melanoma samples, 15 benign nevus samples and in 10 normal skin non-matched samples. In total, 12 malignant melanoma samples were positive for NFIB expression, five benign nevus samples were positive for NFIB expression, no normal skin sample was positive for NFIB expression. Notably, NFIB was

widely distributed in melanoma samples with a cytonuclear staining pattern (data not shown). A significantly higher expression of NFIB was observed in the melanoma specimens, compared with benign pigmented nevus and normal human skin (Fig. 1A). Furthermore, mRNA expression data from the Haqq and Talantov Oncomine datasets supported these findings (Fig. 1B).

The Oncomine datasets were also used to explore the relationship between NFIB expression levels and overall survival. The log-rank test and Kaplan-Meier survival analysis indicated that high NFIB expression was associated with lower overall survival rate, relative to the NFIB low-expression group (Fig. 1C). This indicated that NFIB may serve as a poor

Figure 2. Detection of knockdown efficiency in melanoma cells transfected with NFIB-siRNA. Statistical analysis of wound healing rates in (C) A375 and (D) A875 cells. ** $P < 0.01$. NFIB, nuclear factor I/B; siRNA, small interfering RNA; NC, negative control. Magnification, $\times 100$.

prognostic indicator for melanoma and could be associated with the aggressiveness of melanoma cells.

In addition, western blotting suggested that NFIB expression levels were also elevated in the A375, A875 and SK-MEL1 melanoma cell lines, compared with the normal human keratinocyte HaCaT cell line (Fig. 1D).

NFIB expression promotes migration and invasion in melanoma cell lines. To further investigate the role of NFIB on malignancy in melanoma, NFIB expression was silenced in

A375 and A875 cells using transfection with NFIB-siRNA. Detection of knockdown efficiency was done by RT-qPCR and western blot analysis. NFIB expression was notably dropped in melanoma cell lines using transfection with NFIB-siRNA compared with NC-siRNA (Fig. 2). Subsequently, the role of NFIB on migration and invasion in melanoma cell lines was evaluated in wound healing and Transwell assays. Transfection with NFIB-siRNA significantly reduced the migratory capacity of both A375 and A875 cells, compared with NC-siRNA ($P < 0.01$; Figs. 3 and 4). In addition siRNA-mediated NFIB

silencing also significantly reduced the invasion capacity of both A375 and A875, relative to the NC-siRNA (Fig. 4).

NFIB promotes melanoma cell proliferation and colony formation. Considering that NFIB is highly expressed in human malignant melanoma, the present study sought to investigate whether NFIB affects colony formation and proliferation of melanoma cells. In CCK-8 assays, proliferative ability was significantly reduced in NFIB-silenced melanoma cell lines relative to their respective NC-siRNA controls (Fig. 5A and B). Interestingly, the inhibition effect on the proliferation of melanoma cells began to appear in the first 24 h, and peaked between 24 and 48 h, whereas this effect disappeared after 48 h. Furthermore, the colony formation rate of cells transfected with NFIB-siRNA was significantly lower than that of the NC-siRNA group in A375 and A875 cells (Fig. 6B and D).

Furthermore, compared with the NC-siRNA, cells transfected with NFIB-siRNA also exhibited restricted colonies in both size and numbers (Fig. 6A and C). Consequently, these data suggested that NFIB may enhance the malignancy of melanoma cells, by enhancing the proliferative ability.

NFIB expression promotes EMT in melanoma cell lines. A large number of studies have suggested that EMT has an important role in malignant tumors, focusing on malignant behaviors, such as migration and invasion. During the progression of EMT, E-cadherin is known to be downregulated and N-cadherin is upregulated, which reduces the polarity of epithelial cells and weakens the connection with the basement membrane to obtain higher invasion and migration capacities (26). Thus, the present study examined whether NFIB had an effect on melanoma EMT. Morphological changes of the

melanoma cells were observed under TGF- β 1 treatment and NFIB-siRNA transfection. During inverted phase-contrast microscopy, A375 and A875 cells that initially had epithelial morphology developed an elongated fibroblast-like morphology upon exposure to TGF- β 1-induced EMT. In

contrast, the NFIB-siRNA group melanoma cells were closely packed, and the number of cells in the same field of view was higher, compared with the NC-siRNA group, therefore that TGF- β 1 treated NFIB knockdown cells mostly retained their primary epithelial morphology (Fig. 7A). Western blotting

suggested that the downregulation of NFIB was accompanied by relatively higher expression levels of E-cadherin and ZO-1, compared with the control groups. Conversely, relatively low expression levels of N-cadherin and VIM were associated with the NFIB-siRNA transfected cells (Fig. 7B and C). Overall, these data indicated that NFIB can promote EMT in melanoma cells.

NFIB positively regulates EMT by modulating ZEB1 in melanoma cell lines. To further elucidate the specific molecular mechanism of NFIB in the regulation of EMT in melanoma cells, the A375 and A875 cell lines were transfected with NFIB-cDNA groups or NC-cDNA. The overexpression was detected by RT-qPCR and western blot analysis. NFIB expression was overexpressed in A375 and A875 cells using transfection with NFIB-cDNA compared with NC-cDNA (Fig. 8).

In gastrointestinal epithelial tumors, it has been documented that NFIB is closely related to tumor EMT and promotes the occurrence of EMT in tumor cells by upregulating the expression of SNAI1. It was speculated that NFIB imbued its functions in melanoma by modulating its downstream signaling molecules. ZEB1 has been studied in various tumors and served an important role in EMT. However, the association between NFIB and ZEB1 remains unclear; thus, the present study proceeded to explore this in melanoma. In line with the data obtained from melanoma cells in western blotting, NFIB overexpression was associated with elevated ZEB1 and N-cadherin, while the expression of E-cadherin was downregulated (Fig. 9A and B). Supporting this, NFIB silencing downregulated ZEB1 in A375 and A875 cells, compared with NC-siRNA (Fig. 9C and D), indicating that ZEB1 was associated with NFIB in the regulation of EMT in melanoma.

Discussion

NFIB is a member of the NFI nuclear transcription factor family. NFIB plays an important role in the development of normal embryos and the formation and development of various organs by participating in DNA replication and transcription and can be detected and localized in the nucleus at the early stages of murine embryonic development at 14.5 days (27,28). Accumulating studies indicate that NFIB is closely related to the occurrence of malignant tumors through gene fusion, especially in adenoid cystic carcinoma (29). However, some scholars have pointed out that NFIB may have tumor-suppressive effects as rearrangement leads to NFIB gene truncation and loss of function, together with other related genes, such as NFIB-AIG1, NFIB-MANIA1 and NFIB-NKAIN2 (30-32). Due to this contradictory, double-sided effect of NFIB, which is characterized by both oncogenic and tumor-suppressive activity, the role of NFIB in melanoma remains unclear.

The present study demonstrated that NFIB was upregulated in human melanoma samples, relative to nevus and normal skin samples. Furthermore, NFIB expression was associated with a poor prognosis in melanoma. These are consistent with previous observational data in patients with non-small-cell lung cancer (31). Moreover, the present study revealed that high expression of NFIB was associated with

poor prognosis in patients with melanoma. Consistent with the aforementioned NSCLC study, NFIB is overexpressed and regulates cell viability and proliferation during transformation of murine SCLC, where NFIB amplification is ~15% of primary human SCLC (33).

Based on this evidence, and to further understand the biological functions of NFIB in melanoma cell lines, siRNA-mediated silencing of NFIB was employed to explore the role of this molecule. NFIB silencing inhibited melanoma cell proliferation, colony formation, as well as cell migration and invasion. The cell cycle of melanoma cells was analyzed; however, the experimental results were not satisfactory, and there is no suggestion that there was an association between NFIB expression and the cell cycle in melanoma (data not shown). However, in another study, NFIB knockdown in TP53-mutated triple-negative breast cancer cells promoted cell death, triggered cell cycle arrest and enhanced sensitivity to docetaxel, a first-line chemotherapeutic drug in breast cancer treatment (34). These results suggest that NFIB might serve an important role in melanoma.

A growing number of studies have proposed the behavior of EMT to be a reversible biological process that can regulate migration and invasion in human melanoma (11,35,36). To examine the underlying biological functions by which NFIB promotes migration and invasion in melanoma cells, functional experiments were performed, through which it was uncovered that NFIB had a positive effect on the occurrence of EMT. A recent study revealed that NFIB was involved in the EMT process in colorectal cancer by encompassing various downstream effector molecules (22,37). Western blots were not conducted on the groups treated with TGF- β 1, therefore further experimentation is needed to analyze this. Considering that NFIB regulates numerous cancer-related pathways, the downstream signaling pathway is of great significance for NFIB in the development of melanoma.

ZEB1 is a well-characterized transcription factor that facilitates tumor invasion and metastasis through an EMT-independent mechanism in carcinoma cells (12,38-40). Since ZEB1 belongs to the ZEB family and binds the E-box sequence CACCT, which has two possible binding sites for NFIB, finding a connection between NFIB would be useful to understand the oncogenic functions of NFIB in melanoma (41). Thus, it was hypothesized that NFIB might regulate ZEB1 to influence the EMT of melanoma. The present data support the idea that NFIB overexpression can increase ZEB1 expression. Conversely, the silencing of NFIB could repress ZEB1. However, the present conclusion only provides a new site for NFIB to regulate the biological process in melanoma; further extensive research is needed to verify this hypothesis and determine whether there is an NFIB-ZEB1 axis that modulates the process of EMT. Besides, additional *in vivo*, cell cycle and apoptosis assay experiments are worth conducting to determine whether NFIB contributes to other aspects of melanoma malignancy or if there exist ZEB2-related or other signaling pathways that are also linked with the function of NFIB in melanoma. Collectively, the present findings may hold promising insights into NFIB as a novel prognostic biomarker to predict prognosis and potential therapeutic target in melanoma.
