## ABSTRACT

**Introduction:** Childhood maltreatment (CM) and depression are serious global issues with high prevalence and lifelong impacts on physical and mental health. CM has been proposed as a modifiable risk factor for depression that, if prevented, may contribute to a reduction in the global incidence of depressive disorders. Despite this, there is a paucity of reviews examining the strength of the association between these variables. The aim of this systematic review and meta-analysis was to evaluate the empirical evidence and determine if CM is supported as a preventable risk factor for depression.

**Methods:** A search was performed in July 2024 for all peer-reviewed journal articles written in English examining the relationship between CM and adult depression in the electronic databases *EBSCOhost*, *Proquest*, and *Embase*. Studies were included in this review if they measured maltreatment before 18 years of age as the independent variable and adult depression as the dependent variable. Studies were excluded if the outcome variable was grouped with comorbidity and if they did not report primary quantitative data. A total of 77 studies with 516,302 participants met the inclusion criteria for review.

**Results:** A random-effects meta-analysis was used to generate a pooled odds ratio from 87 effect estimates and demonstrated that individuals with a history of any CM are 2.5 times more likely to experience adult depression ( $OR = 2.49$  [95% CI: 2.25–2.76]). This increase in odds remained regardless of how the primary studies screened for depression.

**Conclusions:** These findings confirmed the strong association between the experience of CM and adult depression. High heterogeneity in the meta-analytic results also suggested that further research is required that applies consistent adjustments for comorbidities and confounding factors and examines the temporal relationship between the variables to establish causality.

## 1 | Introduction

Depression is a common and distressing health condition that has a complicated etiology and is difficult to measure, diagnose, and treat [1]. Depressive disorders have an estimated 12-month global prevalence of 5% [2] and reports of lifetime prevalence rates range from 10% in retrospective studies [3] to more than 30% in prospective studies [4]. Depression contributes significantly to the global disease burden and is a leading cause of disability worldwide [5].

It also imposes a substantial economic burden [6] with an approximated worldwide cost nearing US\$1 trillion and an estimated loss of 12 billion productive workdays each year [7]. Evidence on the efficacy of treatments for depression is mixed [8] and despite an increase in therapeutic options and availability, there continues to be a treatment-prevalence paradox where the incidence of depression is increasing [9]. As such, identifying and addressing modifiable developmental risk factors for depression may play an important role in reducing its prevalence [10, 11].

## Summary

- This review demonstrates a strong association between the experience of childhood maltreatment and the development of depression in adulthood.
- This association remains substantial regardless of how depression is measured.
- Findings highlight that childhood maltreatment may play a role as a modifiable risk factor in the complex etiology of depression.
- Most studies included in the review were from high-income, industrialized countries.
- There was variability in how studies adjusted for confounding and moderating factors.

Growing evidence suggests a strong link between exposure to childhood maltreatment (CM) and the development of depression [12, 13]. CM is the experience of any form of abuse (physical, emotional, and sexual), neglect (physical and emotional), or household instability (e.g., parental substance abuse, exposure to intimate partner violence, parental separation, household mental illness, and parental incarceration) before the age of 18 years [14]. Similar to depression, CM is a significant global issue that has lifelong impacts on health and wellbeing [3]. A meta-analysis of prevalence data from 206 studies across 22 countries estimated that the pooled incidence for a single type of maltreatment was 22.4%, while the experience of four or more types of maltreatment was 16.1% [15]. However, the true global prevalence may be much higher since many countries (particularly low- and middle-income countries) do not have official statistics available [7].

Experiencing CM has been associated with the diagnosis of psychiatric disorders [16], increased health-risk behaviors [17], and early mortality [18]. In the context of depression, studies have found that individuals with a history of CM endure more severe symptoms, earlier onset, higher recurrence rates, and increased incidence of comorbidities than individuals who have not experienced CM [19, 20]. The relationship between CM and depression is complex, and research suggests it may be influenced by several confounding factors, including genetic and environmental contributors, and moderators such as age, gender, and ethnicity [21–24]. Nonetheless, the experience of CM appears to be a strong predictor of depression, and it has been proposed that the neurobiological mechanisms underlying this link are alterations to stress response systems [25]. As a form of early-life stress, CM may contribute to depression through hyperactivation of the hypothalamic–pituitary–adrenal axis response, structural and functional changes in the prefrontal cortex, amygdala, and hippocampus, and an increased immunological inflammatory response [25–27]. These biological correlates of stress and depression are empirically well supported and provide a strong grounding for an association between CM and adult depression.

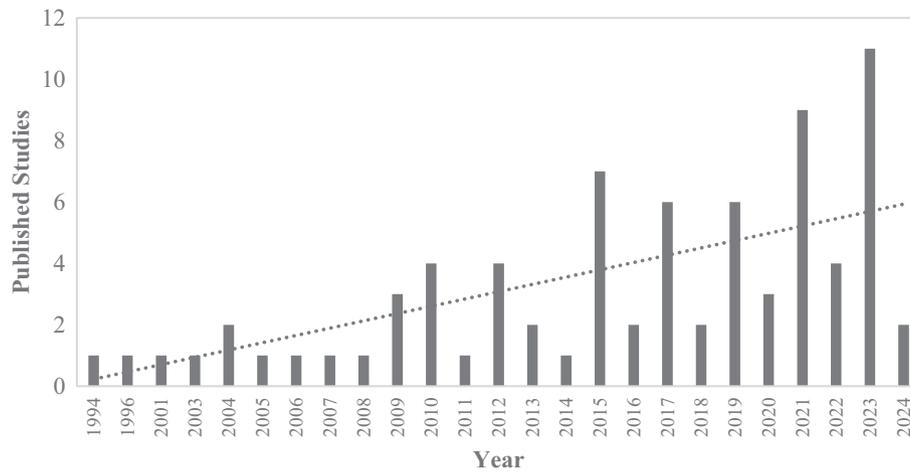

CM has been described as an avoidable social problem that could be stemmed by the introduction of preventative policies and practices [3, 28]. Evidence suggests that risk factors for CM are globally consistent but require a dynamic context-driven response across various social and cultural environments [29, 30]. The WHO [7] advocates for a multisectoral approach to prevention, including

caregiver support, education programs, initiatives addressing norms and values, increased child protection laws, and additional support services. This organization also recommends increased international support and global investment [7] which has been recognized in the United Nations Sustainable Development Goals 16.2 [31] and has resulted in several countries implementing national frameworks for CM prevention [32, 33].

As an avoidable phenomenon, CM has been proposed as an important modifiable risk factor for adult depression [25]. Yet there is a paucity of reviews and meta-analyses synthesizing the evidence of this association. An investigation by Nelson et al. [34] found that individuals with any experience of childhood abuse or neglect were almost three times more likely to develop depression in adulthood. However, that review employed a narrow definition of CM that was limited to the two classes of abuse and neglect. Additionally, the primary effect estimates included in that meta-analysis were not delineated according to the screening method used to measure the variables. As such, the findings of that review may be limited as research suggests there is only a moderate agreement between self-report measures of depression and diagnostic methods such as structured clinical interview [35–37]. Studies have shown that estimates of depression prevalence rates are much higher using self-report scales and that failure to distinguish between screening methods may result in an overestimation of effect [35–37]. Furthermore, the systematic literature search by Nelson et al. [34] was performed in November 2013, and an updated search in July 2024 indicated that there has been a substantial growth in published studies over this 11-year period (see Figure 1). As such, an updated synthesis of the evidence for CM as a risk factor for adult depression is necessary.

A systematic review and meta-analysis by Gardner et al. [38] assessed the effect of five subtypes of CM on the development of anxiety and depression disorders in population-based samples. That study found a strong relationship between depressive disorders and all CM subtypes that remained regardless of the depression screening method used. Nevertheless, a key limitation of that research was the exclusion of studies that did not report odds ratio or risk ratio effect estimates. This resulted in a low number of estimates being included in some of the meta-analytic calculations and may also have excluded studies that did not support the association between the variables under investigation. Other reviews have examined the sub-elements of the association between CM and depression, such as gender differences [23], the timing effect of maltreatment exposure [39], and outcomes experienced by children and adolescents [40], but these analyses do not allow determination of the overall magnitude of the relationship.

The aim of the current review was to address the gaps in the literature by providing an updated systematic and comprehensive examination of the empirical evidence to assess the nature and magnitude of the relationship between CM and adult depression. It was hypothesized that there would be a robust association between the experience of CM and increased odds of developing depression. It was also hypothesized that the estimated effect would be less significant in studies where a diagnostic screening method was used for depression compared with those studies using a self-report scale or questionnaire. These findings were considered in light of determining if CM prevention might be a theoretically viable approach to reducing the global prevalence of depression.

**FIGURE 1** | Trend of published studies examining the association between childhood maltreatment and adult depression. This figure shows the growth trend in the number of published studies examining the association between CM and adult depression as identified in the current systematic review.

## 2 | Methods

### 2.1 | Search Strategy

To identify studies of the association between CM and adult depression, a systematic search was performed in July 2024 for peer-reviewed journal articles published over the preceding 50 years in the electronic databases *EBSCOhost*, *Proquest*, and *Embase*. The search terms used were “childhood maltreatment,” “child abuse,” “adverse childhood experiences,” “depression,” “depressive disorder,” “depressive symptoms,” and “major depressive disorder.” Where available, advanced search options were selected to allow each database to apply related words and equivalent terms to the search criteria. In addition, a manual search was undertaken in the reference lists of identified articles, previous reviews, and meta-analyses. Before the application of inclusion criteria, the first author screened study titles and abstracts for alignment with the research topic.

### 2.2 | Selection Criteria

Studies were included in this review if they measured CM before 18 years of age as the independent variable and adult depression (> 18 years) as the dependent variable. No exclusions were made according to the sample used. Studies were excluded if (1) they were not written in English, (2) they were not original, peer-reviewed journal articles, (3) the outcome variable was grouped with a comorbidity (e.g., depression and anxiety combined), and (4) they did not report primary quantitative data for CM and depression. Reviews, case studies, opinion articles, books, and qualitative studies were not included in this review.

### 2.3 | Data Extraction and Quality Assessment

Descriptive information was extracted and entered into an Excel spreadsheet, including the author/s, journal name, year of publication, study location, sample size, number of males and females, source of participants, age (range or mean), measurement

of CM, measurement of depression, subtype of CM, and effect size estimates. Where the study measured CM as binary (either present or absent) the subtype was listed as “Any” Whenever possible, adjusted effect estimates were extracted to ensure the impact of CM was measured without confounding variables. The quality of the included studies was evaluated using the *Newcastle-Ottawa Quality Assessment Scale* (Table S1; [41]). Eleven quality characteristics were assessed, and each was presumed to contribute equally to the overall quality valuation of the study. No minimum quality threshold was set for the inclusion of studies in the review and meta-analysis; however, ratings were used to perform sensitivity analyses to determine the impact of study quality on the meta-analysis outcomes.

### 2.4 | Statistical Analysis

A meta-analysis was performed to examine the overall association between the experience of CM and the development of depression in adulthood using effect estimates from the studies that reported CM as a binary variable (present/absent). Additional meta-analyses were performed according to how the primary studies screened for depression and CM (self-report scale or a clinical interview) to allow for comparison of the pooled effect sizes. In all instances, odds ratios were selected as the effect estimate for investigation due to the frequency of its use among the reviewed studies (~77%) and to allow for easy interpretation of the probability of depression.

Odds ratios were either obtained directly from the studies or were calculated for studies where sufficient data were available. A random-effects model was selected for all meta-analyses to account for between-study variance. Cochran’s Q and  $I^2$  statistics were estimated to evaluate study heterogeneity [42]. The meta-analyses were performed using *Stata* statistical software version 15. Multiple sensitivity analyses were undertaken to determine if the overall findings were robust and remained consistent. The undue influence of individual studies on the results of the meta-analysis was assessed by omitting each study in turn. Furthermore, subgroup analyses were performed by sorting

studies according to the screening instrument used for identifying CM and depression. Finally, a meta-analysis was performed on high-quality studies only (which were defined as those studies that scored eight points or higher on the *Newcastle-Ottawa Quality Assessment Scale*). The possibility of publication bias was assessed by viewing funnel plots and performing a trim and fill analysis [43].

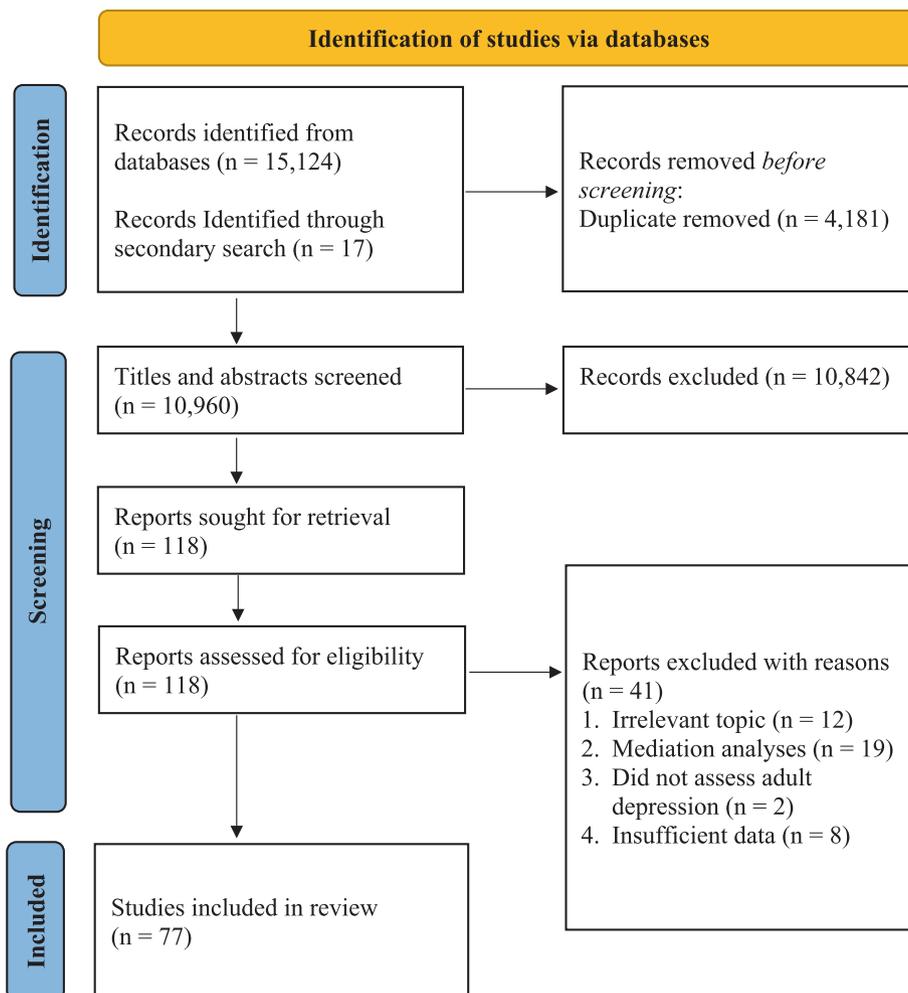

### 3 | Results

The process for the identification and selection of studies (*PRISMA* flowchart) is shown in Figure 2. The database search identified 15,124 peer-reviewed journal articles and a secondary manual search using the reference lists of previous review articles identified an additional 17 studies. The search results included 4181 duplicate reports which were subsequently removed. The titles and abstracts of the remaining 10,960 studies were screened by the first author for alignment with the research topic. After the exclusion of unrelated studies, 118 full-text articles were retrieved for assessment of inclusion eligibility. A total of 77 studies met the criteria for review and 67 of these reported effect estimates that met the criteria for inclusion in one or more of the meta-analyses. A detailed description of each

of the studies is displayed in Table 1 including all major findings related to adult depression.

There were a total of 516,302 participants across the 77 reviewed studies, with the sample sizes ranging from 113 individuals in the smallest study to 60,598 in the largest. The median sample size for all studies was 2288 participants. Just over 40% of the studies (31/77) were conducted in the United States of America, with the remainder occurring in Australia, Botswana, Brazil, Canada, China, Finland, France, Germany, Iran, Iraq, Ireland, Italy, Japan, Mexico, Netherlands, New Zealand, Pakistan, South Africa, South Korea, Turkey, Uganda, and the United Kingdom. Approximately 69% (53/77) of the studies were published in the last 10 years. The earliest report was published in 1994 and the most recent in 2024. The average score on the *Newcastle-Ottawa Quality Assessment Scale* was 6.79, with results ranging from 4.00 to 9.00 (see Table S1).

There was variability in the moderating and confounding factors assessed by the reviewed studies. Models that adjusted for the sex and age of the participants were the most common (71.4%), followed by participants' education level (50.6%), income (29.8%), ethnicity (28.5%) and marital status (27.3%). A limited number of studies assessed the influence of empirically supported

confounders of CM and depression, including income/socioeconomic status (41.5%), chronic illness (6%), body mass index (6%), and negative affectivity/neuroticism (5%). None of the 77 studies examined genetic predisposition as a confounding factor.

### 3.1 | CM Measurement

The majority of the investigations included in this review used self-report screening methods to measure CM (66 out of 77 studies). The most utilized test was the *Adverse Childhood Experiences Questionnaire* (ACE; [14]) which was administered in ~39% of reviewed studies (30/77) either in its original form or as an international variant. The ACE questionnaire is a brief and well-validated instrument that is widely used in research and clinical practice as a screening tool for CM and as a risk index for future negative health outcomes [157]. The scale is based on the cumulative risk model of CM, which proposes that the lifetime risk of poor health outcomes is positively associated with an accumulation of adverse childhood experiences [158]. The ACE is a yes/no 10-item self-report questionnaire evaluating an individual's recall of childhood exposure to abuse, neglect, and household instability [14, 157]. The number of yes responses is totaled to provide the CM accumulation index, which is subsequently interpreted as the risk score.

Another popular self-reporting screening tool was the Childhood Trauma Questionnaire (CTQ) which was used in 11 of the 77 reviewed studies. Like the ACE scale, the CTQ has been assessed as highly reliable and well-validated and has questions that delineate between each of the five subtypes of CM [157]. However, it differs from the ACE by using a five-point Likert scale rather than dichotomous (yes/no) items and by including a validity subscale of three items that assess the reliability of the information reported by the participants [157]. Other self-reporting screening methods used included the Maltreatment and Abuse Chronology of Exposure Scale (MACE), the Child Abuse and Trauma Scale (CATS), and the Conflict Tactic Scales (CTS). Aside from these, two of the reviewed studies used primary care records from child protection agencies, and nine studies used clinical interviews administered by trained psychologists or psychiatrists.

### 3.2 | Depression Measurement

Fewer than half of the reviewed studies screened for depression using clinical interviews (28/77) administered by trained professionals based on the diagnostic criteria for depressive disorders set by the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed., text rev.; DSM-5-TR; American Psychiatric Association [APA], [121]). The remaining studies (49/77) used self-report scales or questionnaires to assess depressive symptoms. The short form (10 items) of the *Centre for Epidemiological Studies Depression* scale (CES-D; [128]) was the most frequently used self-report measure, which was utilized in 15 of the 77 analyses. The CES-D has been assessed as having high validity and internal consistency in both its long and short forms [159, 160]. Other frequently used screening tools were the *Patient Health Questionnaire* (10/77; [149])

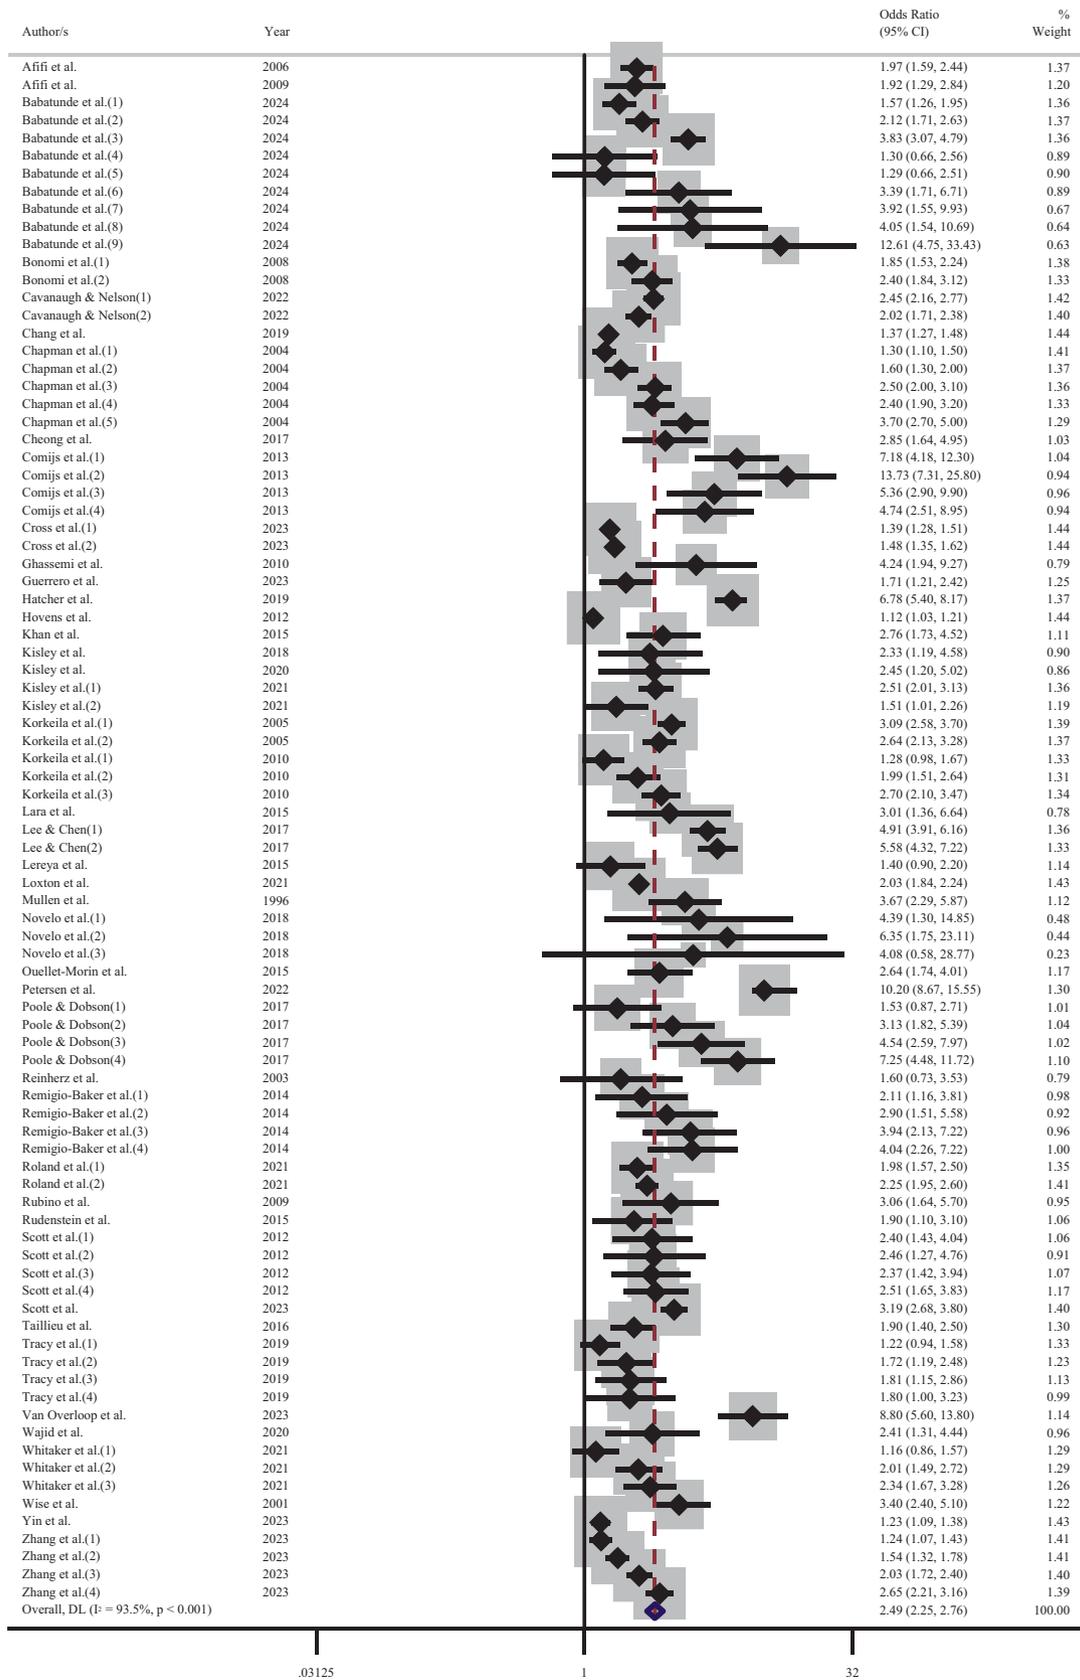

and the *Beck Depression Inventory* (7/77; [122]). While the diagnostic interview is recommended as the 'gold standard' for the assessment of depression by the DSM-5-TR [121], evidence suggests that the above retrospective scales have a strong correlation to the DSM-5-TR criteria and comparable reliability and internal consistency [161, 162]. Nonetheless, research suggests that the use of self-report screening methods for depression can produce poor consistency with diagnostic measures and often overestimates the prevalence of depressive symptoms [35–37].

### 3.3 | The Association Between CM and Adult Depression

The 77 studies included in this review reported 101 effect estimates of the relationship between CM as an independent variable and adult depression as a dependent variable. Each of these demonstrated that exposure to CM increased the likelihood of experiencing adult depression. The lowest increase in odds was 1.1 times [69] while the largest was 12.6 times the probability [49]. The random-effects meta-analysis of the association between any CM and adult depression included 87 effect estimates, which were drawn from 44 studies (see Figure 3). The results of this analysis indicated that individuals with a history of any CM are approximately two-and-a-half times more likely to experience adult depression (OR = 2.49 [95% CI: 2.25–2.76]) than individuals without a history of CM.

Further meta-analyses were performed to determine the influence of depression and CM screening methods on the pooled effect size. An analysis of those studies that screened for depression using self-report measures indicated that the experience of CM increased the odds of adult depression by 2.6 times (OR = 2.60 [95% CI: 2.26–2.99]; Figure 4). Comparatively, a meta-analysis of reports that used a diagnostic clinical interview demonstrated an increase of odds 2.3 times (OR = 2.34 [95% CI: 2.00–2.73]; Figure 5). The proximity of these odds ratios for self-report versus clinical interview suggests that, while self-report measures of depression may result in a slight overestimation of the effect, the substantial association between the CM and adult depression remains evident. Similarly, exploration of CM screening methods demonstrated that the pooled effect size of studies using a self-report questionnaire (OR = 2.58 [95% CI: 2.30–2.90]; Figure 6) was marginally higher, but not significantly different than those studies using a clinical interview (OR = 2.13 [95% CI: 1.64–2.77]; Figure 7).

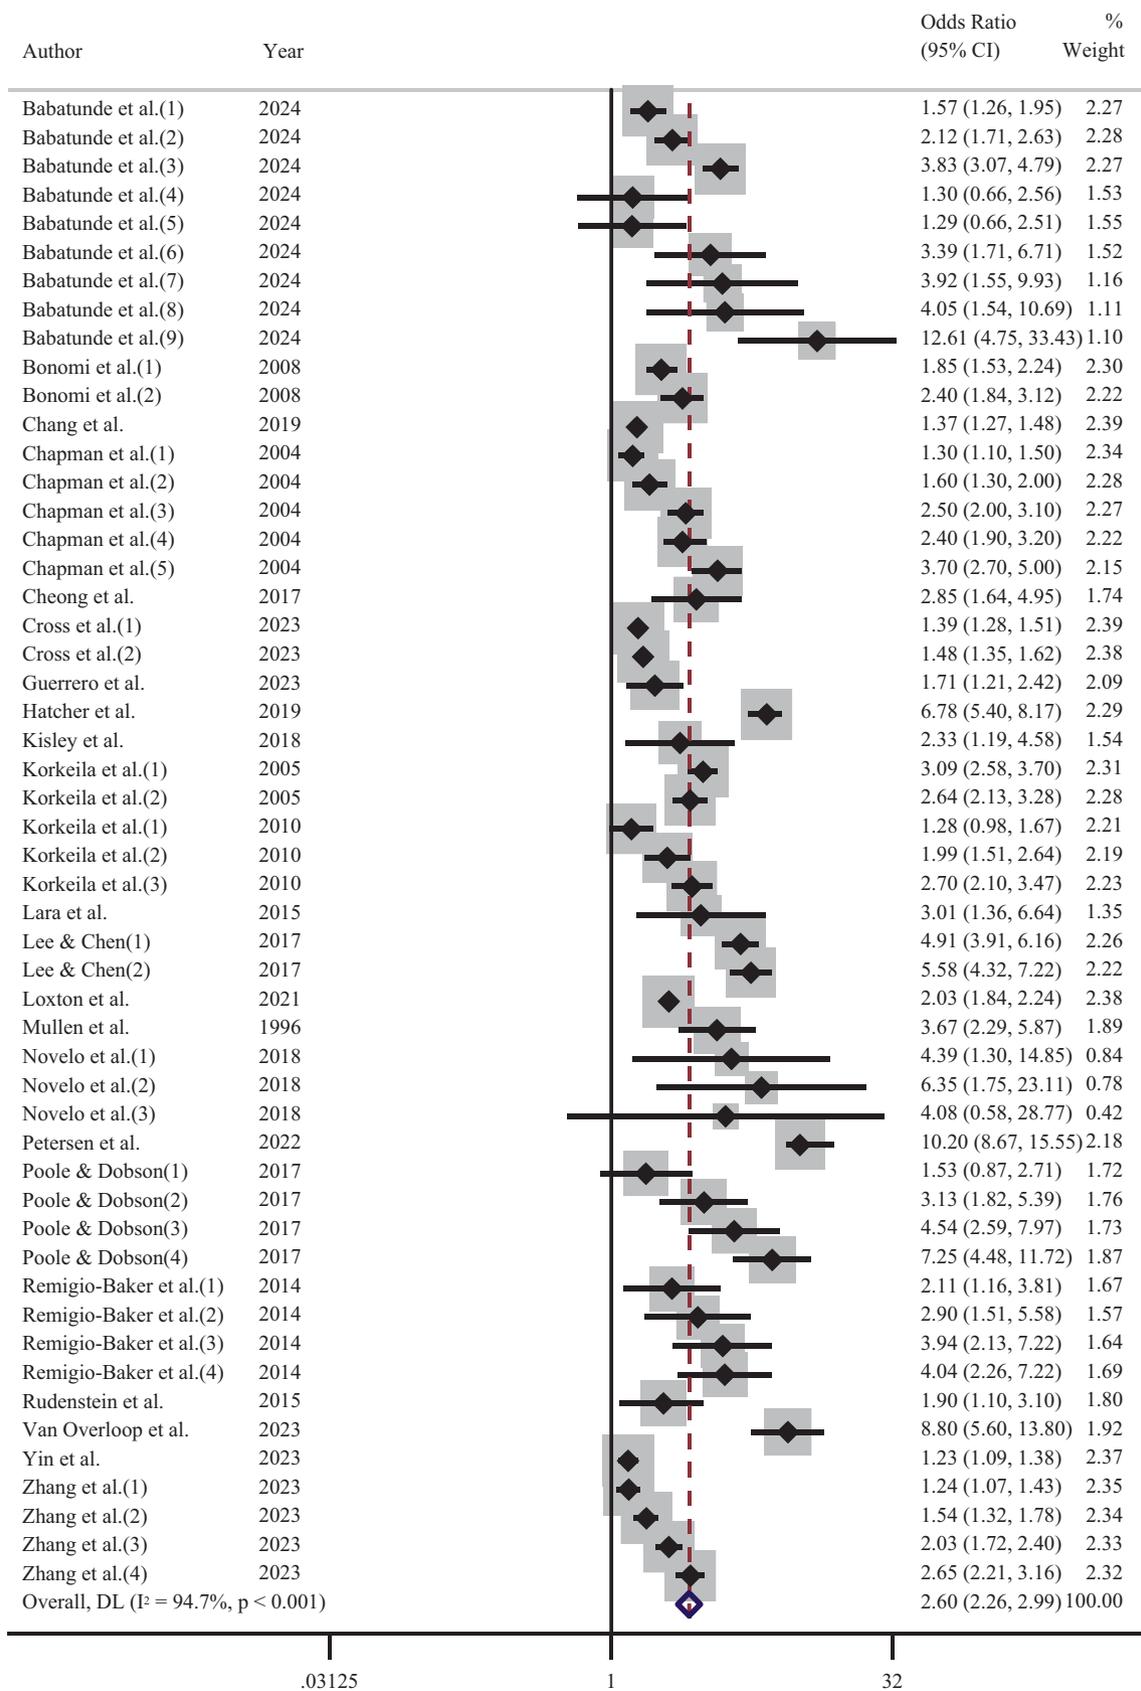

There was significant heterogeneity in the overall meta-analysis ( $I^2 = 93.5\%$ ; Cochran's  $Q = 1319.02$ ,  $df = 86$ ,  $p < 0.001$ ) which suggests that the reported samples differed substantially between studies. This heterogeneity remained after the studies were grouped according to CM screening method (self-report:  $I^2 = 93.7\%$ ; Cochran's  $Q = 1118.95$ ,  $df = 70$ ,  $p < 0.001$ , clinical interview:  $I^2 = 90.4\%$ ; Cochran's  $Q = 156.15$ ,  $df = 15$ ,  $p < 0.001$ ) and depression measure (self-report:  $I^2 = 94.7\%$ ; Cochran's  $Q = 961.24$ ,  $df = 51$ ,  $p < 0.001$ , diagnostic interview:  $I^2 = 90.5\%$ ; Cochran's  $Q = 357.69$ ,  $df = 34$ ,  $p < 0.001$ ). These outcomes confirmed the choice to use a random-effects model for the meta-analysis to account for between-study variance. Further examination of the data was undertaken to evaluate

**FIGURE 3** | Meta-analysis of the association between the experience of childhood maltreatment and adult depression.

the influence of each independent study on the collective findings. Eighty-seven permutations of the meta-analysis were computed, omitting one study at a time, using the *Stata*

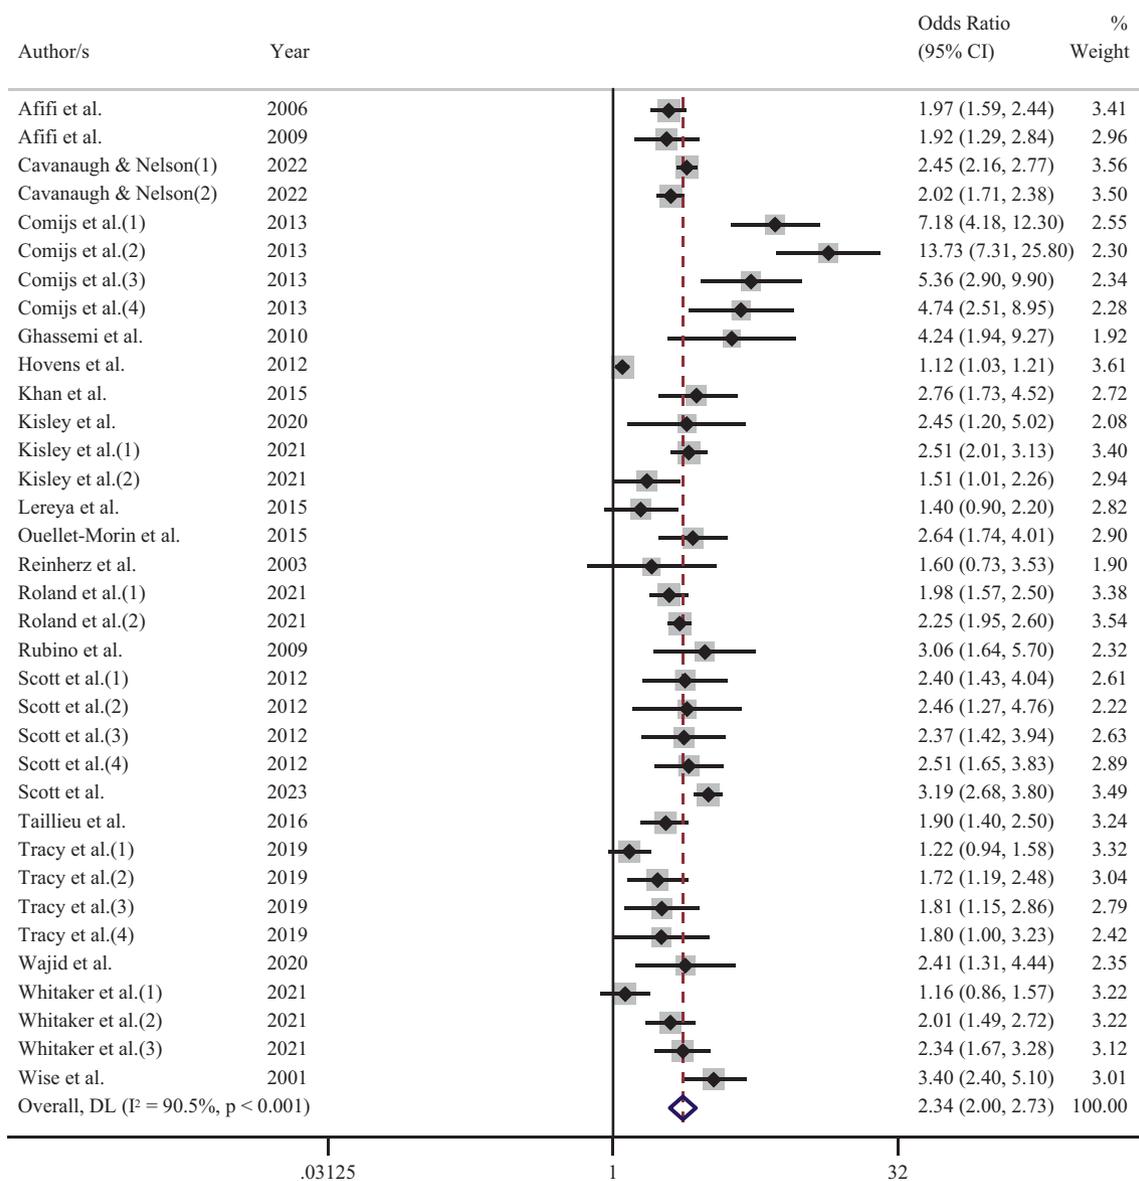

statistical software (see Figure S1). These calculations demonstrated that no individual study had an undue influence on the pooled effect estimate of the meta-analysis.

**FIGURE 4** | Meta-analysis of the association between the experience of childhood maltreatment and adult depression (self-reported).

The subgroup analysis of CM screening instruments showed minimal variance between the pooled effect estimates (see Table S2). The ACE questionnaire was the most popular CM

self-report tool, and it demonstrated only a slightly higher pooled effect estimate (OR = 2.36 [95% CI: 2.08–2.66]) than clinically administered interviews (OR = 2.18 [95% CI:

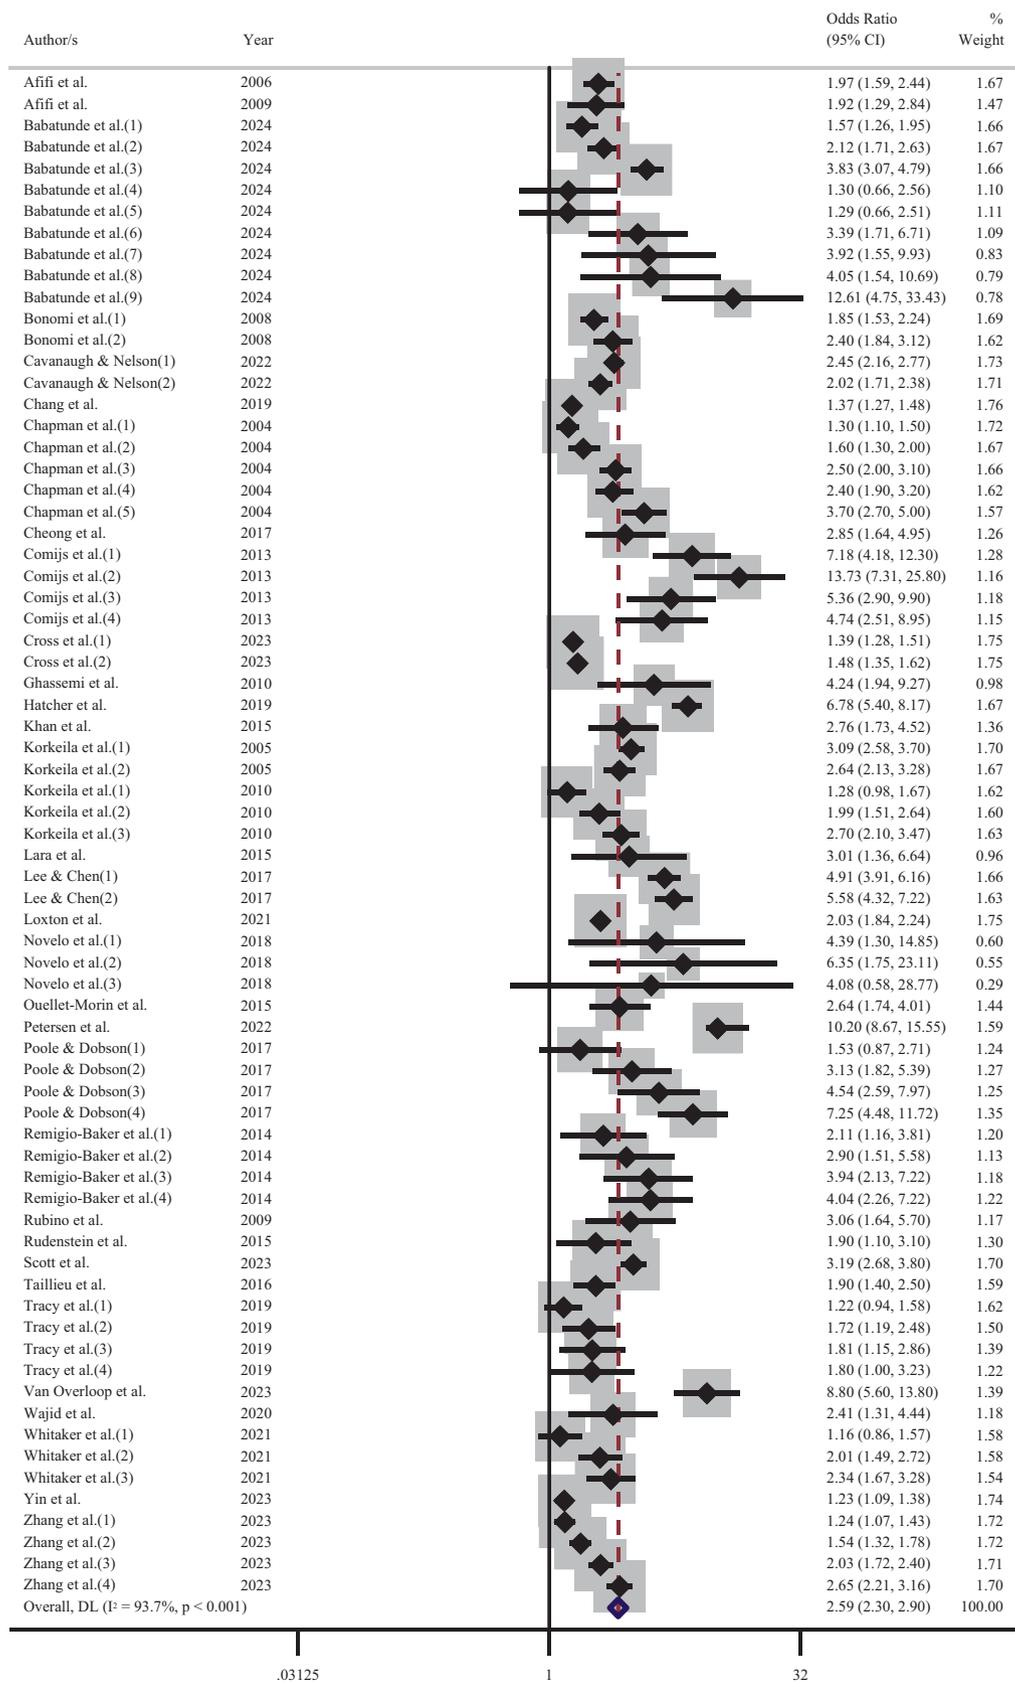

**FIGURE 5** | Meta-analysis of the association between the experience of childhood maltreatment and adult depression (diagnosed in clinical interview).

1.77–2.70]). The analysis of depression screening subgroups indicated that the pooled effect estimate from studies that used diagnostic interviews was slightly higher (OR = 2.27 [95% CI: 1.95–2.66]) than the most popular self-report instrument, the CES-D (OR = 2.11 [95% CI: 1.72–2.59]; Table S3). The sensitivity analysis of studies identified as high-quality revealed that CM increased the odds of adult depression by 2.36 times (OR = 2.36 [95% CI: 2.06–2.71]; Figure S2). This pooled effect estimate is slightly lower than the primary meta-analysis (OR = 2.49 [95% CI: 2.25–2.76]).

#### 4 | Discussion

This study addressed the limitations of previous research by providing a comprehensive review and meta-analysis of the association between CM and adult depression. The findings confirmed that experiencing CM increased the odds of developing

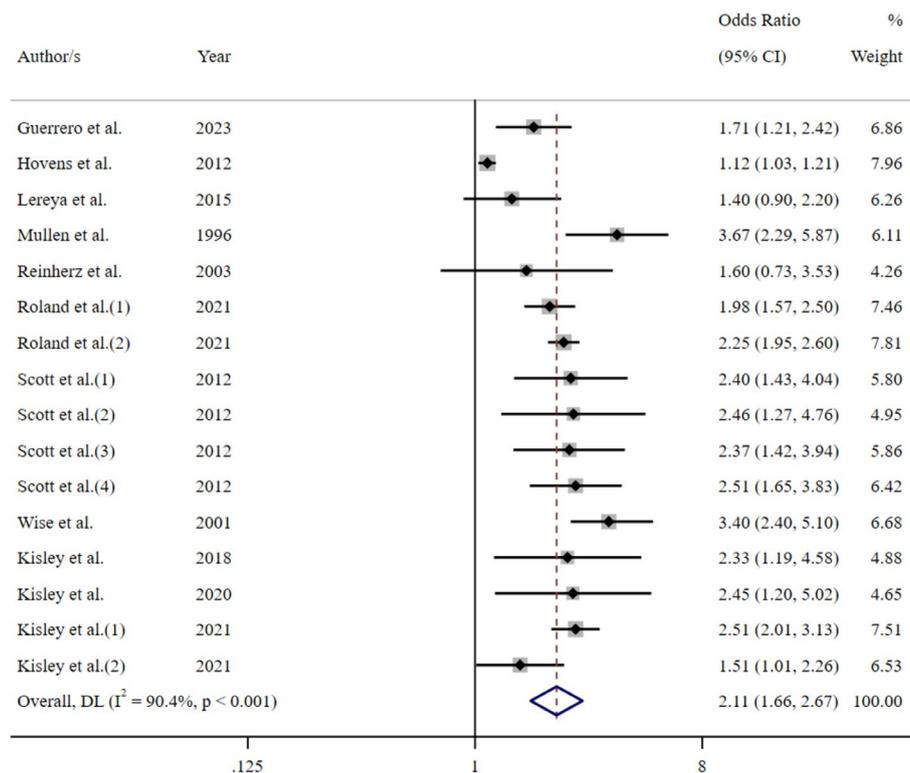

depression in adulthood by just under 2.5 times. These results are consistent with previous systematic reviews and meta-analyses [23, 34, 38–40]; however, the current study further established that the magnitude of this association substantially remained regardless of whether depression was self-reported or diagnosed by clinical interview. Research has suggested that reliance on self-report measures for depression can overestimate prevalence and subsequently positively skew meta-analytic results [35, 36]. However, in the current study, the subgroup analysis stratified by depression screening method indicated that studies that employed a diagnostic interview estimated slightly higher odds than the most popular self-report questionnaire. Comparatively, the CM screening method used slightly influenced the strength of the pooled effect estimate. Studies that identified CM using a clinical interview demonstrated a lower pooled effect estimate (OR = 2.13 [95% CI: 1.64–2.77]) than studies that used a self-report method (OR = 2.58 [95% CI: 2.30–2.90]). This outcome is contrary to previous research which found a strong synergy between interviewer-rated

**FIGURE 6** | Meta-analysis of the association between childhood maltreatment (self-reported) and adult depression.

retrospective reports and self-report questionnaires [163]. As such, it may be an important focus of future research to establish the inter-rater reliability of CM screening methods.

Other meta-analyses have determined marginally higher pooled effect sizes than the current study. Nelson et al. [34] found that CM nearly tripled the risk of adult depression (OR = 2.81 [95%

**FIGURE 7** | Meta-analysis of the association between childhood maltreatment (clinical interview) and adult depression.

CI: 2.35–3.36]) in their assessment of studies published before 2013. However, that study restricted the definition of CM to abuse or neglect and did not include exposure to household instability, which limits the direct comparison of outcomes from that study with those found here. Similarly, Li et al. [39] identified a statistically significant relationship between CM and depression ( $r=0.17$  [95% CI: 0.15–0.18],  $p < 0.0001$ ); however, less than half of the studies included in that analysis were of adult populations. In their meta-analysis of studies published before March 2018, Gardner et al. [38] found results consistent with the current study (OR = 2.48 [95% CI: 2.14–2.87]). However, that investigation included predominantly children and adolescent samples and had a low number of primary effect estimates (22) included in that meta-analysis in comparison to the current study. Subsequently, the findings of the current analysis provide a unique and updated evaluation of the empirical evidence supporting the association between CM and adult depression.

Despite the comprehensive nature of this review, the results should be considered in the context of potential limitations. First, there was variability across the reviewed studies in the analysis of moderating and confounding variables. While the majority of studies adjusted for sociodemographic factors, empirically supported confounders, such as socioeconomic status, genetic predisposition, and parental psychopathology, were not consistently considered. Subsequently, the contribution of CM to the development of adult depression may be overestimated given depression's complex etiology. Second, the findings may have limited generalizability due to the elevated number of samples from high-income, industrialized countries. For example, investigations from the United States of America represented 40% of the reviewed studies and 39% of the effect estimates included in the meta-analyses. There were also a number of

studies that used convenience sampling, such as university students, clinical participants, and employees, which may attract volunteer bias and limit the significance of findings to the broader population. Finally, there was inconsistency in study design and variable measurement across studies that precluded some effect estimates from being included in the overall analysis. The majority of reports used a retrospective design (66 out of 77 studies), while only two studies used primary care records from a child protection agency to confirm participant experience of CM. Nonetheless, nine of the reviewed studies used a prospective design and reported findings that were similar to the overall meta-analysis outcomes or demonstrated a stronger association.

There were also limitations that should be considered when evaluating the results of the systematic review and meta-analyses. The selective publication of studies with significant findings and the underreporting of null findings may introduce bias and influence the outcomes of the analysis. Furthermore, the exclusion of non-English language studies may also introduce bias. There was high heterogeneity in the meta-analyses, which indicated variability between the included studies. This is consistent with previous reviews of the association between CM and depression [22, 34] and may be a consequence of the complex interplay of contributors involved in the development of depression. While several sensitivity analyses were undertaken in an attempt to explain this heterogeneity, it is proposed that the inconsistencies in how effect estimates were adjusted for moderators may play an important role. It should also be noted that while the findings of this review demonstrate a strong and consistent association between CM and adult depression, the majority of included studies were cross-sectional and cannot support the conclusion of a causal relationship. Causality requires a clear temporal

association and analytic adjustment for numerous covariates. Instead, it is proposed that the findings indicate that CM may be one of many important modifiable contributors to the development of depression.

The findings of this review have important implications for future research and may contribute to the understanding of the complex etiology of depression. In a clinical context, the findings suggest that early intervention and preventative strategies for depression may benefit from the inclusion of treatment strategies and support processes for survivors of CM. Further research is required examining the contribution of CM to depression in the context of the many others empirically supported confounding and moderating factors. Evidence is also required from low-income, developing countries to complement the well-established findings of high-income, industrialized countries. There is an opportunity for longitudinal research examining the temporal association between CM and depression to aid in the determination of a causal relationship. There is also an opportunity to examine the relationship between the different forms of maltreatment and the symptom-based subtypes of depression that may allow targeted treatment models. Finally, future studies should aim for consistency in the measurement of CM and depression, and a comprehensive approach to adjusting for moderating and confounding variables.

## 5 | Conclusions

Depression is a highly prevalent and debilitating health condition that continues to increase in incidence despite improved treatment approaches and broader therapeutic access. There is strong evidence suggesting that the experience of CM may be one of the many factors contributing to the development of depression in adulthood. As a preventable phenomenon, CM may play an important role among these contributors as a modifiable risk factor for depression. The findings of this systematic review and meta-analysis suggest that CM more than doubles the odds of adulthood depression. These results extend the findings of previous research by establishing that this association persists regardless of the screening methods used.

### Author Contributions

C.B.W. conceptualized the systematic review design, developed the search strategy, extracted data, and carried out the statistical analyses. C.B.W. and C.F.S. collaborated in the article writing. V.B., I.E., and K.V. contributed to developing and finalizing the manuscript.
