ABSTRACT

Background. Soil respiration (R_S) plays an important role in the concentration of atmospheric CO₂ and thus in global climate patterns. Due to the feedback between R_S and climate, it is important to investigate R_S responses to climate warming.

Methods. A soil warming experiment was conducted to explore R_S responses and temperature sensitivity (Q_{10}) to climate warming in subtropical forests in Southwestern China, and infrared radiators were used to simulate climate warming.

Results. Warming treatment increased the soil temperature and R_S value by 1.4 °C and 7.3%, respectively, and decreased the soil water level by 4.2% (%/%). Both one- and two-factor regressions showed that warming increased the Q_{10} values by 89.1% and 67.4%, respectively. The effects of water on Q_{10} show a parabolic relationship to the soil water sensitivity coefficient. Both R_S and Q_{10} show no acclimation to climate warming, suggesting that global warming will accelerate soil carbon release.

INTRODUCTION

Soil is the largest pool of organic carbon in the terrestrial ecosystem, playing a crucial role in the global carbon cycle. R_S serves as a significant source of atmospheric CO₂ (Friedlingstein et al., 2006; Bond-Lamberty & Thomson, 2010) and is regulated by temperature (Giardina et al., 2014). Therefore, slight changes in R_S due to global warming will increase levels of atmospheric CO₂ and thereby be feed back into the global climate system.

Numerous studies have shown that R_S rates typically increase over the course of short-term soil warming experiments (Gonzalez-Meler et al., 2017; Xue & Tang, 2018; Zhao et al., 2018) and long-term warming experiments (Noh et al., 2016; Zhou et al., 2016) and likely due to the promotion of soil microbial activity and a lack of restrictions on soil organic matter during warming treatment periods. Some studies also report that warming decreases R_S levels during long-term warming experiments (Melillo et al., 2002; Marañón Jiménez et al., 2017; García-Palacios et al., 2018) and mainly due to the excessive consumption of carbon pools. Some studies show that short-term warming treatment can also decrease R_S levels (Schindlbacher et al., 2012; Liu et al., 2016) due to droughts caused by climate

warming. Warming treatment also has no significant effect on R_S (Wang et al., 2017). Therefore, R_S responses to warming remain unclear and must be studied further.

The Q_{10} of R_S is an important parameter of how R_S responds to warming. Some studies show that warming treatment reduces the Q_{10} value (Boone et al., 1998; Luo et al., 2001; Wang et al., 2016; Noh et al., 2017) due to soil microorganism adaptation to warming. This adaptation may be due to a decrease in soil microbial carbon utilization and enzyme activity (Allison, Wallenstein & Bradford, 2010) and to changes in soil microbial community structures (Ziegler et al., 2013). Simultaneously, the Q_{10} level exhibits no adaptive response to climate warming (Reth et al., 2009) and even increases under warming conditions (Cao et al., 2018; Zhao et al., 2018).

Acclimatization has been found to decrease for R_S and Q_{10} under warming conditions (Luo et al., 2001; Melillo et al., 2002). However, a previous study shows that heterotrophic respiration in subtropical forests of Southwestern China show no acclimation to warming (Wu et al., 2016). While it is important to identify effects of warming on subtropical forests (Wu et al., 2016), R_S and Q_{10} responses to warming in such forests remain unclear. We hypothesized that R_S and Q_{10} show no acclimation to warming in the forests. To test this hypothesis, we conducted control and warming experiments on subtropical forests of the Ailao Mountains to identify the effects of warming on R_S and Q_{10} levels in these forests.

MATERIALS & METHODS

Site description

The experimental field is located at site of the Ailaoshan Station for Subtropical Forest Ecosystem Studies (24°32'N, 101°01'E; 2,480 m above sea level) of the Chinese Ecological Research Network. According to monitoring data for 2002 to 2011, the annual average air temperature was 11.3 °C; the maximum air temperature was 15.6 °C (July); the minimum temperature was 5.7 °C (January); the annual average precipitation level was 1,778 mm, and rainfall levels reached close to 85% of total annual rainfall for the rainy season (May–October) (Wu et al., 2014). The main type of soil found in the area yellowish-brown with a pH value of 4.5; soil organic carbon levels reach 303.8 g kg⁻¹ and total nitrogen levels reach 18.38 g kg⁻¹ in the humus horizon (Chan et al., 2006). The main species found in the area include *Lithocarpus hancei*, *Castanopsis wattii*, *Schima noronhae*, and *Lithocarpus xylocarpus* (Wu et al., 2014).

Experimental design

In the subtropical forest, six plots of 1 m × 1 m were randomly selected, and two treatments were established, including control and warming treatments with three replicates. A carbonizing infrared radiator was applied as the heat radiation source for the warming treatment, and a 200-watt carbon infrared radiant heating lamp (each lamp was 90 cm long and each lampshade was 100 cm long, 15 cm wide, and 10 cm deep) was placed approximately 1.0 m above the sample side of each plot. A continuous heating mode was adopted from June 2016 to May 2017, supplying continuous power except during power outages. In each plot, a PVC pipe (inner diameter of 20 cm and soil depth of two cm) was

placed to directly couple with an external PVC pipe (outer diameter of 20 cm, upper seal base opening and height of 20 cm) for further measurements of R_S .

Data collection and calculations

Soil CO₂ efflux was measured monthly using a gas analyser (Li-820; Li-Cor, Lincoln, NE, USA) between 9:00 and 11:00 AM (Beijing Time) to measure R_S levels. Soil temperatures (T , °C) were measured with a digital thermometer (6310; Spectrum, Illinois, USA), and soil water content (W , %) was measured via time domain reflectometry (MP-KIT; Beijing Channel, Beijing, China) at a depth of 50 mm. The R_S rate was calculated as follows:

$$R_S = \frac{V \cdot P}{R \cdot S \cdot T_a} \cdot \frac{dc}{dt} \quad (1)$$

where R_S is the soil CO₂ efflux value ($\mu\text{mol m}^{-2} \text{s}^{-1}$); V is the chamber volume (m^3); S is the chamber area (m^2); R is the gas constant ($8.314 \text{ Pa m}^3 \text{ k}^{-1} \text{ mol}^{-1}$); T_a is air temperature (K); P is air pressure (Pa), and dc/dt is the slope of variations in CO₂ concentrations overtime for the measurement period.

We used a one-factor regression to determine the relationship between R_S and T and a two-factor regression to determine relationships of R_S with T and W . The regression equations applied are as follows (Xu & Qi, 2001a; Liu et al., 2018):

$$R_S = a \cdot e^{bT} \quad (2)$$

$$R_S = a \cdot e^{bT} \cdot W^c \quad (3)$$

Where a , b and c are estimated from the regressions; b is the soil Q_{10} coefficient, and c is the soil water sensitivity coefficient.

Q_{10} is calculated using the following equation (Luo et al., 2001):

$$Q_{10} = e^{10b} \quad (4)$$

Where b is derived from Eqs. (2) and (3).

Different Q_{10} values derived from the one- and two-factor regressions are attributable to soil water effects, and the effect on Q_{10} ($WE_{Q_{10}}$) was calculated with the following equation:

$$WE_{Q_{10}} = \frac{Q_{10\text{-one-factor}} - Q_{10\text{-two-factor}}}{Q_{10\text{-two-factor}}} \times 100\% \quad (5)$$

The parameters were estimated from the models listed above using the nonlinear regression dynamic fit wizard, and t tests were used to test differences in the R_S , T , W , and Q_{10} values of the control and warming treatments (Version 12; Systat Software, Inc., Point Richmond, California, USA).

RESULTS

Effect of warming on soil environment factors

The warming treatment increased the soil temperature but did not change seasonal variation patterns (Fig. 1A). Mean annual soil temperatures measured from the control and warming treatments were recorded as 11.1 ± 0.1 °C and 12.5 ± 0.1 °C, respectively, and warming significantly increased the soil temperature by 1.4 °C (Fig. 1B). During the measurement period, the warming treatment significantly affected soil temperatures during both the dry and rainy seasons (Fig. 1B). However, warming did not change soil water content levels, and in terms of seasonal variations, we found no significant differences between dry season, rainy season and yearly trends (Figs. 1C & 1D). Mean annual soil water levels measured from the control and warming treatments were recorded as $30.3 \pm 3.0\%$ (v/v) and $29.0 \pm 2.8\%$ (v/v), respectively, reduced by 4.2% (%/%) (Fig. 1D).

Effect of warming on soil respiration

Soil warming increased R_S levels in the rainy season but suppressed them in the dry season (Fig. 2A). No significant differences in means of the control and warming treatments were observed across dry season, rainy season, and annual period (Fig. 2B). In the dry season, mean values of the two treatments were recorded as 2.68 ± 0.47 $\mu\text{mol m}^{-2}\text{s}^{-1}$ and 2.27 ± 0.28 $\mu\text{mol m}^{-2}\text{s}^{-1}$, respectively, with the warming treatments showing a reduction of 15.0%. In the rainy season, mean values for the two treatments were recorded as 5.50 ± 0.79 $\mu\text{mol m}^{-2}\text{s}^{-1}$ and 6.50 ± 0.32 $\mu\text{mol m}^{-2}\text{s}^{-1}$, respectively, with the warming treatments showing an increase of 18.1%. The mean annual R_S for the two treatments was recorded as 4.09 ± 0.28 $\mu\text{mol m}^{-2}\text{s}^{-1}$ and 4.39 ± 0.25 $\mu\text{mol m}^{-2}\text{s}^{-1}$ where values increased by 7.3% during the warming treatment.

Effect of warming on temperature sensitivity

From one-factor regression model results, the Q_{10} values of the control and warming treatments were recorded as 2.6 ± 0.7 and 4.9 ± 0.3 , respectively, and warming significantly increased the Q_{10} value by 89.1%. According to two-factor regression model results, the Q_{10} values reached 2.0 ± 0.5 and 3.3 ± 0.2 , respectively, and warming significantly increased the Q_{10} values by 67.4% (Fig. 3). One- and two-factor regression parameters are given in Table 1. WEQ_{10} increased when the c values fell below 0.779 and decreased when the c values exceeded 0.779 (Fig. 4).

DISCUSSION

Warming treatment can effectively increase soil temperatures (Wang et al., 2019; Li et al., 2018) and thereby decrease soil water levels (Wang et al., 2014; Chen et al., 2018). In our experiment, warming treatment resulted in higher soil temperatures than those observed in the control treatment (Figs. 1A & 1B), and the soil water levels were found to be lower than those of the control treatment (Figs. 1C & 1D). A number of previous studies show that warming experiments significantly increase R_S levels (Zheng et al., 2009; Zhao et al., 2018; Zou et al., 2018). In our experiment, the warming treatment resulted in an increase in the average R_S by 7.3% due to soil warming of 1.4 °C. These findings are less significant

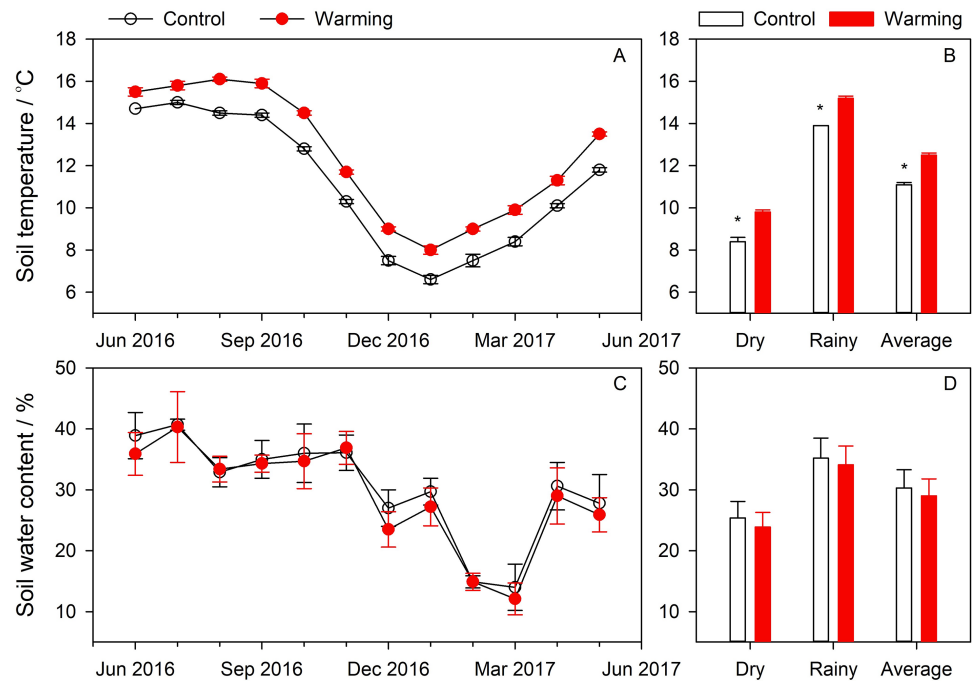

Figure 1 Seasonal variations of soil temperature (A) and soil water content (C), and comparisons of soil temperature (B) and soil water content (D) between control and warming treatment.

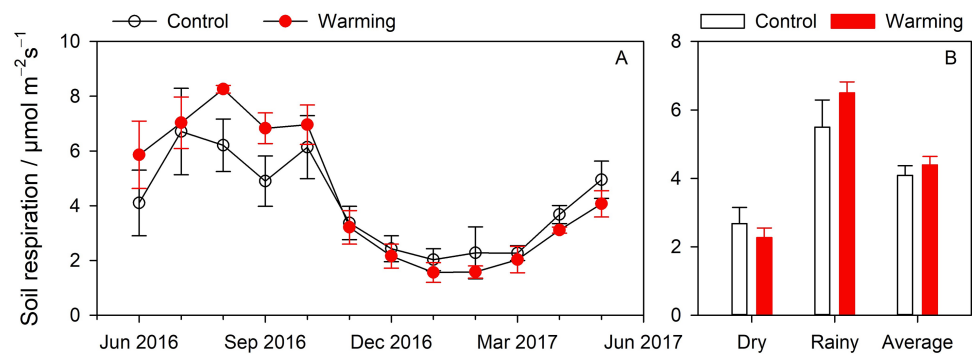

Figure 2 Seasonal variations (A) and comparison (B) of soil respiration between control and warming treatment.

Full-size [DOI: 10.7717/peerj.7721/fig-2](https://doi.org/10.7717/peerj.7721/fig-2)

than others reported. For instance, R_S has been found to increase by 32% with 4 °C of warming (Noh *et al.*, 2016), by 28% with 2.5 °C of warming (Bamminger, Poll & Marhan, 2018), and even by 7.1% with 0.47 °C of warming (Xia *et al.*, 2009). Wu *et al.* (2016) found the warming effects on soil carbon flux to be positively related to the warming effects on soil temperature. The warming effects on soil temperature observed in the present study are less significant (or stronger) than those reported above, leading to lesser (or stronger) warming effects on R_S . In the present study, warming treatment was found to have no significant effect on R_S , agreeing with the results found for another subtropical forest in

Guangxi, China (Wang et al., 2017). However, 1.7 °C warmer temperatures significantly increase heterotrophic respiration in subtropical forests in Guangxi, China, corroborating results reported for our study region (Wu et al., 2016). Therefore, our results showing no significant effects are likely attributable to the fact that warming suppresses autotrophic respiration (Wang et al., 2017).

We also found the warming treatment to have different effects during the dry and rainy seasons (Figs. 2A and 2B). The study area is located in a monsoon region where temperature and humidity levels are synchronized and where R_S is affected by effects of interactions between soil temperature and soil water content (Table 1). In the rainy season, soil water levels were high while decreases in soil water content due to warming were limited (3.2%, %/%). Therefore, soil water content had no restrictive effects. However, in the dry season, soil water levels and soil temperatures were both low and positive effects of soil warming were less significant than negative effects of soil water content due to warming, as soil drought due to warming can offset warming effects (Schindlbacher et al., 2012). Therefore, R_S levels were found to be lower under the warming treatment than under the control treatment in the dry season.

Figure 4 Relationship between soil water sensitivity and effect of soil water on temperature sensitivity.

Full-size DOI: [10.7717/peerj.7721/fig-4](https://doi.org/10.7717/peerj.7721/fig-4)

While warming has been widely shown to decrease the Q_{10} values (Luo *et al.*, 2001; Li *et al.*, 2016; Noh *et al.*, 2017), we found warming to increase Q_{10} values consistent with previous studies (Teramoto *et al.*, 2018; Zhao *et al.*, 2018). Warming treatment decreased basal respiration in the dry season and increased respiration in the rainy season, thereby increasing seasonal amplitudes (Fig. 2). However, warming did not change seasonal amplitudes of soil temperature (Fig. 1A), leading to higher Q_{10} values from regression models. Soil is intrinsically sensitive to temperature as determined by substrate properties and initial temperature conditions (Davidson & Janssens, 2006). Q_{10} levels of R_S calculated from equation models show Q_{10} affected by intrinsic Q_{10} and environmental factors (e.g., soil water conditions) (Davidson & Janssens, 2006). R_S is directly influenced by substrate supplies, soil temperatures, and effects of soil temperature and soil water content on substrate diffusion and availability (Davidson, Janssens & Luo, 2006). Therefore, both soil temperature and soil water content affect Q_{10} values, explaining 93% of seasonal variations in Q_{10} (Xu & Qi, 2001b).

In this study, two models (Eqs. (2) and (3)) were used to reflect the relationship between R_S and soil temperature and to calculate the Q_{10} values. GLM analysis suggests that both the treatment and model had significant effects on the Q_{10} values (Table 2). The one-factor model only considers relationship between R_S and soil temperature, while the two-factor model considers the effects of both soil temperature and soil water content on R_S . As the Q_{10} values were calculated from these models, any factors affecting R_S would affect them. Therefore, soil water availability affects Q_{10} (Zhong, Shen & Fu, 2016). The Q_{10} values derived from the one-factor model are significantly higher than those derived from the two-factor model, as the Q_{10} value calculated from the one-factor model covers soil water effects. In comparing the two models, we measured the effects of water on Q_{10} ($WE_{Q_{10}}$) and found the relationship between $WE_{Q_{10}}$ and the soil water sensitivity coefficient (c value in

Table 2 Result of GLM analysis on temperature sensitivity.

Source	<i>t</i> value	<i>p</i> value
Treatment	5.961	<0.01
Method	−3.664	<0.01

Eq. (3)) (Fig. 4). $WE_{Q_{10}}$ exhibits a parabolic regression relationship with the *c* value (peak value of 0.779).

Soil respiration is driven by soil microbial rhizosphere activities and is affected by soil temperature and the soil water content. Therefore, warming effects on R_S and Q_{10} are affected by the above factors. Warming treatment can change substrate supplies and microbial activities or communities (Wang et al., 2019; Li et al., 2018). Therefore, soil aggregate protection and microbial communities can also affect the Q_{10} values (Qin et al., 2019). In the present study, we focused on warming effects on R_S and Q_{10} . More studies on soil properties and microbial communities should be conducted.

CONCLUSIONS

In summary, our warming experiment increased the soil temperature by 1.4 °C, decreased the soil water level by 4.2% (%/%), and increased the R_S value by 7.3%. Both one- and two-factor regressions show that warming increased the Q_{10} values by 89.1% and 67.4%, respectively. Both R_S and its Q_{10} show no acclimation to climate warming, suggesting that global warming will accelerate soil carbon release.
