ABSTRACT

Patients with polymerase epsilon (*POLE*) exonuclease domain mutation (EDM) exhibits distinct clinical characteristics and extremely high tumor mutation burden (TMB). There is a paucity of data on the therapeutic efficacy of immune checkpoint inhibitors (ICIs) for the treatment of colorectal cancer liver metastases (CRLM) patients with *POLE* EDM. Clinical characteristics, radiological and pathological response, as well as oncological outcomes of four CRLM patients harboring *POLE* EDM and treated by ICI plus chemotherapy were retrospectively collected and analyzed. TMB and genomic mutation profiling were also assessed in resected CRLM patients harboring different molecular characteristics. The four CRLM patients received toripalimab or sintilimab plus chemotherapy (FOLFOX or FOLFIRI or XELOX) with or without bevacizumab after *POLE* EDM were detected. All four patients achieved a radiological partial response. Staged or simultaneous complete surgical resection of the primary tumor and liver metastases was conducted. Pathological complete response was achieved in all four patients. After a median follow-up of 14 (range 9–20) months, all four patients maintained non-evidence of disease status until the last follow-up. *POLE* EDM patients showed a larger set of mutational genes compared with non-*POLE* EDM patients. TMB of patients harboring *POLE* EDM was significantly higher than those with microsatellite instability-high (median, 313.92 vs 42.24 mutations/Mb, $p < 0.05$), *POLE* non-EDM (313.92 vs 4.80, $p < 0.001$), and MSS subtypes (313.92 vs 4.80, $p < 0.001$). Despite being a rare phenotype, CRLM patients with *POLE* EDM exhibit ultra-high TMB and, more importantly, significant clinical response to ICI-based combination therapy. Therefore, the complete sequencing of *POLE* exonuclease domains is recommended in CRLM patients clinically.

BACKGROUND

The clinical outcomes of patients with colorectal cancer liver metastases (CRLM) exhibit great heterogeneity. Previous studies revealed that more than 50% of CRLM

patients would experience recurrence after initial liver resection.^{1,2} CRLM patients who respond well to preoperative treatment typically have a favorable prognosis, especially those who achieve pathological complete response (pCR).³ Immune checkpoint inhibitors (ICIs) directed against programmed death-1 (PD1) protein are highly effective and have become the preferred choice for the treatment of patients with mismatch repair-deficient (dMMR) metastatic colorectal cancer.⁴ However, given the small portion of patients with dMMR, more markers that could predict ICI response are urgently needed.

DNA polymerase epsilon (*POLE*) encodes the catalytic subunit of DNA polymerase epsilon, an enzyme involved in DNA replication and repair.⁵ Exonuclease domain mutations of *POLE* (*POLE* EDM) are detected in a variety of malignant tumors, most frequently in endometrial (6%–12%) and colorectal cancer (1%–2%).^{6,7} *POLE* EDM endometrial cancer is characterized by a robust intratumoral T-cell response, possibly because of an abundance of neoantigens caused by extremely high tumor mutation, ultimately leading to an excellent prognosis.⁸ In stage II colorectal cancer, somatic *POLE* EDM display enhanced intratumoral immune responses, evidenced by increased CD8 + tumor infiltration lymphocytes and CD8A expression.⁹

This study examined four CRLM patients harboring the *POLE* EDM who responded to ICI-based combination treatment. The clinical treatment, radiological response, postoperative pathological findings, and oncological outcomes were reported and assessed. Furthermore, we analyzed CD3, CD8, and programmed death-ligand 1

(PDL1) expression levels in tumor tissues as well as the dynamic change of circulating cell-free DNA methylation during treatment. The gene mutation profiling and tumor mutation burden (TMB) of *POLE* EDM patients with resected CRLM patients harboring distinct molecular features, that is, *POLE* non-EDM, microsatellite instability-high (MSI-H) and microsatellite stable (MSS) were also compared.

METHODS

Study design

The design of this study is shown in online supplemental figure S1. A total of four patients diagnosed with CRLM harboring *POLE* EDM and treated by ICI plus chemotherapy between 2019 and 2020 at Sun Yat-sen University Cancer Center, Guangzhou, China, were retrospectively included. Clinical treatment course, radiological response, pathological findings (tumor regression, lymphocyte infiltration), as well as circulating free DNA (cfDNA) methylation dynamics of the four patients were collected and shown (online supplemental figure S1A). Additionally, gene profiles and TMB of these four patients with *POLE* EDM were showed and compared with other 292 resected CRLM patients harboring distinct molecular features, that is, *POLE* non-EDM, MSI-H, and MSS, treated between 2010 and 2020 at our center (online supplemental figure S1B). Patients were categorized into the above four molecular subgroups based on their *POLE* mutation sites (oncogenic mutation or not) and microsatellite status. *POLE* EDM was defined as oncogenic mutations in P286R, S459F, V411L, etc, referring to the list of the oncogenic *POLE* alterations at OncoKB (<https://www.oncokb.org/gene/POLE>).¹⁰ *POLE* non-EDM refers to mutations in the *POLE* non-oncogenic sites, for example, P1832F, R1390H, A25V, etc. We also analyzed the molecular characteristics and TMB of metastatic colorectal cancer from the Memorial Sloan Kettering Cancer Center (MSKCC) cohort.¹¹

Treatment

Patients harboring *POLE* EDM received ICI plus chemotherapy with or without bevacizumab every 2–3 weeks. The ICI used was one of the two humanized IgG4 monoclonal PD-1 antibodies, toripalimab (JS-001, Shanghai Junshi Bioscience)¹² or sintilimab (IBI308, Innovent Biologics and Eli Lilly and Company),¹³ both of which were developed and approved for the treatment of several solid tumors in China. Chemotherapy regimens consisted of fluorouracil and oxaliplatin (FOLFOX or XELOX) or irinotecan (FOLFIRI). Radiological response was assessed using the Response Evaluation Criteria in Solid Tumors V.1.1.¹⁴ Adverse events were graded according to the National Cancer Institute Common Terminology Criteria, V.4.0.

Pathology assessment and immunohistochemistry analysis

A thorough pathological examination of the resected tumors was conducted. No residual tumor cells in

resected specimens (primary tumor, regional lymph nodes, and liver metastases) by routine H&E staining was defined as pCR. Formalin-fixed, paraffin-embedded sections were obtained from both pretreatment biopsies and resection specimens for further examination of CD3+ (ZSGS-BIO, Beijing, China; Catalog No. ZA0503) and CD8+ (ZSGS-BIO, Beijing, China; Catalog No. ZA0508) tumor-infiltrating T lymphocytes using specific antibodies and immunohistochemistry (IHC) analysis. To quantitatively analyze lymphocytes infiltration, we used ImageJ software (<https://imagej.nih.gov/ij/>, National Institute of Health, Bethesda, Maryland, USA) to calculate the number of CD3+ and CD8+ T cells and compared the infiltration level before and after ICI plus chemotherapy by counting the average number of staining lymphocytes in ten random fields (×20). The expression of PD-L1 protein on pretreatment biopsy tissues was determined using mouse monoclonal antibody clone 22C3 pharmDx (Dako).

NPY/SEPT9/WIF1 methylation levels in circulating free DNA

Blood samples were collected at different time points (pretreatment, post-treatment, and postoperatively), and NPY/SEPT9/WIF1 methylation levels in circulating free DNA (meth-cfDNA) were tested. cfDNA was extracted from 2 mL of serum using the QIAamp DNA Blood Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's protocol. DNA bisulfite conversion was then performed using the EZ DNA Methylation Kit (Zymo Research, USA). Finally, a total volume of 20 µL of modified DNA was obtained, which was used immediately for PCR or stored for later use at -20°C. The serum DNA methylation analyses were performed using the QX200TM Droplet DigitalTM PCR System (Bio-Rad).

Next-generation sequencing

All samples subjected to next-generation sequencing (NGS) analysis were required to have >10% of tumor cells identified by IHC. Patients were subjected to a wide panel genomic sequencing (pan-cancer 1021-gene panel, Geneplus Technology) for simultaneous detection of MSI status and mutations in 1021 cancer-related genes, including *KRAS*, *NRAS*, *BRAF*, *HER2*, *TP53*, *SMAD4*, *POLE*, and other genes related to tumor development and carcinogenesis. TMB was defined as the number of somatic non-synonymous mutations per megabase of genome examined. MSI was assessed using MSIsensor.¹⁵

Statistical analysis

Statistical analyses were performed using R software V.3.5.1 (<http://www.r-project.org>). Comparison of TMB between different molecular groups and lymphocyte infiltration before and after ICI treatment were evaluated by the nonparametric Wilcoxon test. $p < 0.05$ at two sides was considered statistically significant.

Table 1 Clinicopathological feature, treatment, and outcome of four CRLM patients harboring *POLE* EDM

RESULTS

Clinical characteristics of the four patients with *POLE* EDM

The clinical characteristics of the four CRLM patients harboring *POLE* EDM are shown in table 1. All four patients were male and three of them were less than 40 years of age. They all harbored the oncogenic *POLE*P286R

mutation in the exonuclease domain. The *POLE* P286R mutation was detected at initial diagnosis in two patients and progressed on first-line systematic chemotherapy in other two patients. The stage of four tumors according to the American Joint Committee on Cancer (eighth edition) in initial diagnosis was cT3-4aN1-2M1a, IVa.

The primary tumor was located in the rectum, ascending colon, sigmoid colon, and transverse colon, respectively. Synchronous liver metastases were the only metastatic site in all four patients. The number of liver metastases was 8, 7, 1, and 5, respectively. The diameter of the largest lesion of liver metastases at initial diagnosis was 8.5 cm, 5.9 cm, 14.6 cm, and 6.7 cm, respectively. Hepatobiliary surgeon-assessed resectability of liver metastases at initial diagnosis were unresectable in one patient, potentially resectable in two patients and resectable in one patient. Fong's Clinical Risk Score¹⁶ amounted to a score of 4 in three patients and 3 in one patient (case 4).

Clinical treatment and radiological response

All four patients received ICI plus chemotherapy after *POLE* P286R mutation was detected. Case 1 received first-line toripalimab plus FOLFOX for 7 cycles and sharp tumor burden reduction was achieved in both liver lesions and primary tumor (online supplemental

figure S2A). Case 2 received first-line FOLFOX and the liver lesions progressed after 3 cycles of treatment. He then received second-line sintilimab and FOLFIRI after *POLE* P286R mutation was detected. A very good partial response (decrease of 80% in diameter) was achieved (figure 1). Case 3 received first-line FOLFOX plus bevacizumab, radiological partial response was achieved and liver metastasectomy was conducted. However, liver recurrence occurred shortly (3 months after liver resection) and second-line sintilimab and FOLFIRI were started after *POLE* P286R mutation was detected (online supplemental figure S2B). Case 4 received first-line toripalimab plus XELOX and bevacizumab for five cycles (online supplemental figure S2C). Both case 3 and case 4 achieved a small partial response (approximately 35% decrease in diameter) after ICI combined treatment.

After systematic ICI plus chemotherapy, all four patients received staged or simultaneous complete surgical

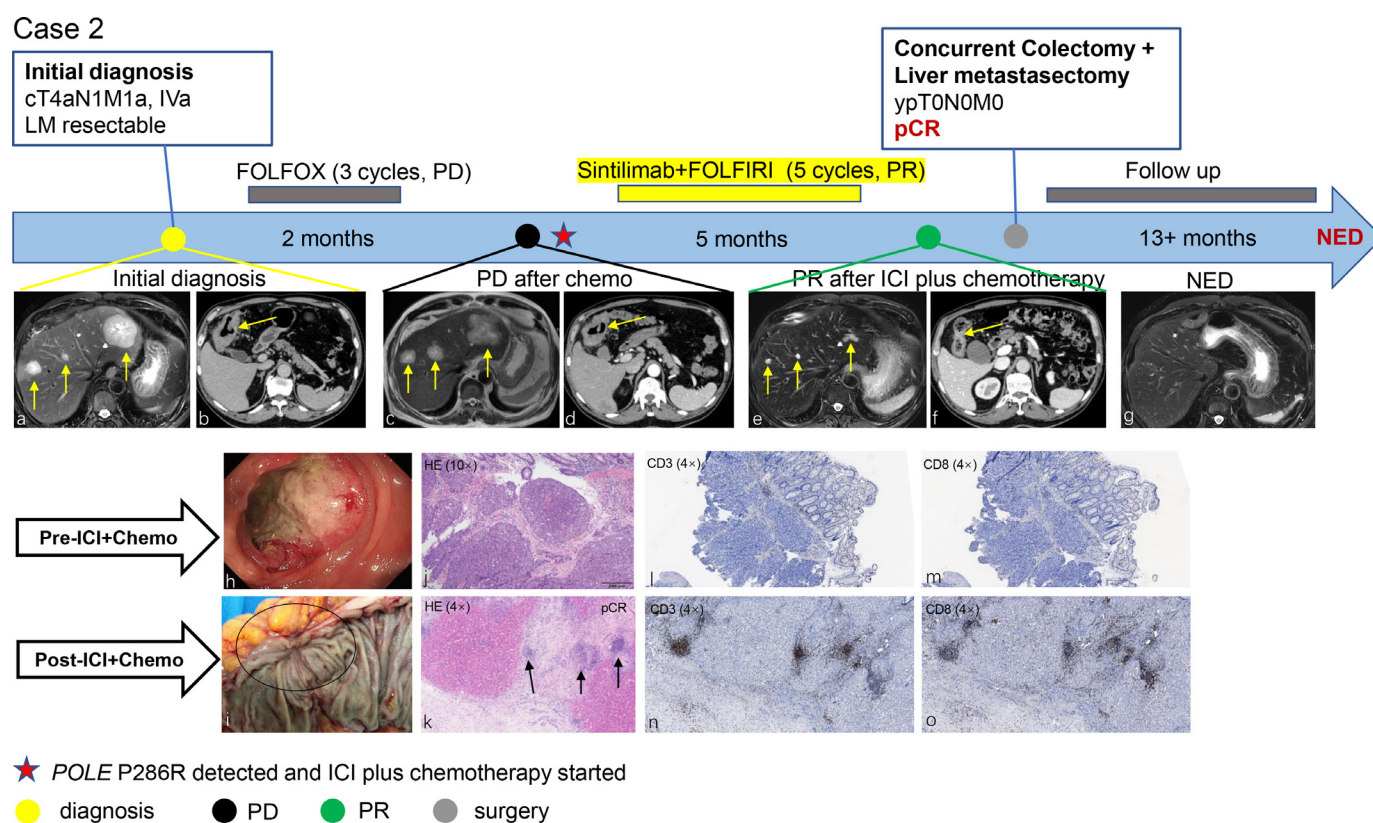

Figure 1 Treatment timeline, radiological and pathological response to second-line sintilimab plus FOLFIRI in a 71-year-old man with stage IVa/cT4aN1M1a, right-sided CRLM harboring *POLE* EDM (case 2). Radiographic imaging shows resectable multiple metastases (A) in different liver segments originating from the ascending colon (B) at initial diagnoses. The patient received first-line chemotherapy (FOLFOX), which progressed shortly. (C, D) Then he received second-line ICI plus chemotherapy (sintilimab + FOLFIRI) and a notable tumor regression could be seen both in liver metastases (E) and primary tumor (F). simultaneous colectomy and liver metastasectomy were then conducted (G). primary tumor at initial diagnosis was observed using colonoscopy (H) and resection specimens of obvious shrunken colon cancer (I) after ICI plus chemotherapy treatment. H&E staining shows primary tumor at initial diagnosis (J) and pathological complete regression of liver metastases (K) after ICI plus chemotherapy. fibrosis and an infiltration with viable density of many lymphocytes (K, arrowheads) could be seen. IHC showing more CD3 and CD8 tumor-infiltrating lymphocytes (TILs) using a serial section following treatment (N, O) tumor tissue compared with pretreatment (I, M). The comparisons were statistically significant ($p < 0.01$). IHC, immunohistochemistry; CRLM, colorectal cancer liver metastases; ICI, immune checkpoint inhibitor; pCR, pathological complete response; PD, progressive disease; PR, partial response.

resection for primary tumor and liver metastases (case 3 only received liver metastasectomy because he had primary tumor resected before ICI treatment). Three of four patients received postoperative ICI monotherapy continually for a total of 1 year (preoperative plus postoperative) and one patient (case 2) refused any postoperative treatment.

PATHOLOGICAL FINDINGS

A thorough pathological examination of the resected tumors was conducted. Massive necrosis tissue and lymphocytes infiltration were detected, while no residual cancer cells were found microscopically both in primary tumor, regional lymphnodes, and metastatic liver lesions in all four patients, indicating pCR was achieved after ICI-based combination treatment (figure 1, online supplemental figure S2).

High CD3 +andCD8+T cell infiltration could be observed in resected specimens after ICI plus chemotherapy. In case 2 and case 3, a significant pretreatment to post-treatment increase in CD3 +andCD8+lymphocytes infiltration was found ($p < 0.05$, Wilcoxon). Weak expression of PD-L1 was found in only one patient (case 1, Combine Positive Score=5) (online supplemental figure S2A), while the other 3 patients showed negative PD-L1 expression.

NPY/SEPT9/WIF1 meth-cfDNA dynamics

Plasma NPY/SEPT9/WIF1 meth-cfDNA was detected in different timepoints (pre-ICI treatment, post-ICI treatment, and postoperatively). The percentage of NPY, SEPT9, and WIF1 meth-cfDNA in the four patients at baseline ranged from 8.64% to 39.05%, from 9.53% to 25.14%, and from 3.73% to 31.55%, respectively. A sharp reduction in NPY/SEPT9/WIF1 meth-cfDNA was seen after ICI-based treatment in all patients. NPY/SEPT9/WIF1 meth-cfDNA level decreased to an almost non-detectable level (nearly 0%) before surgical intervention and remained at a very low level (0%–1%) postoperatively, and thereafter. The dynamic change of NPY/SEPT9/WIF1 meth-cfDNA in plasma was consistent with tumor burden and treatment response. Plasma carcinoembryonic antigen (CEA) changes during treatment in cases 1 and 4 were consistent with NPY/SEPT9/WIF1 meth-cfDNA, while in cases 2 and 3, plasma CEA was within normal limits during the entire disease course (figure 2).

Oncological outcomes and adverse events

After a median follow-up of 14 months (range 9–20), all four patients maintained a non-evidence of disease status until the last follow-up in December 2021. The progression-free survival (defined as from surgery to last follow-up) was 5+, 16+, 4+, and 9+months, respectively.

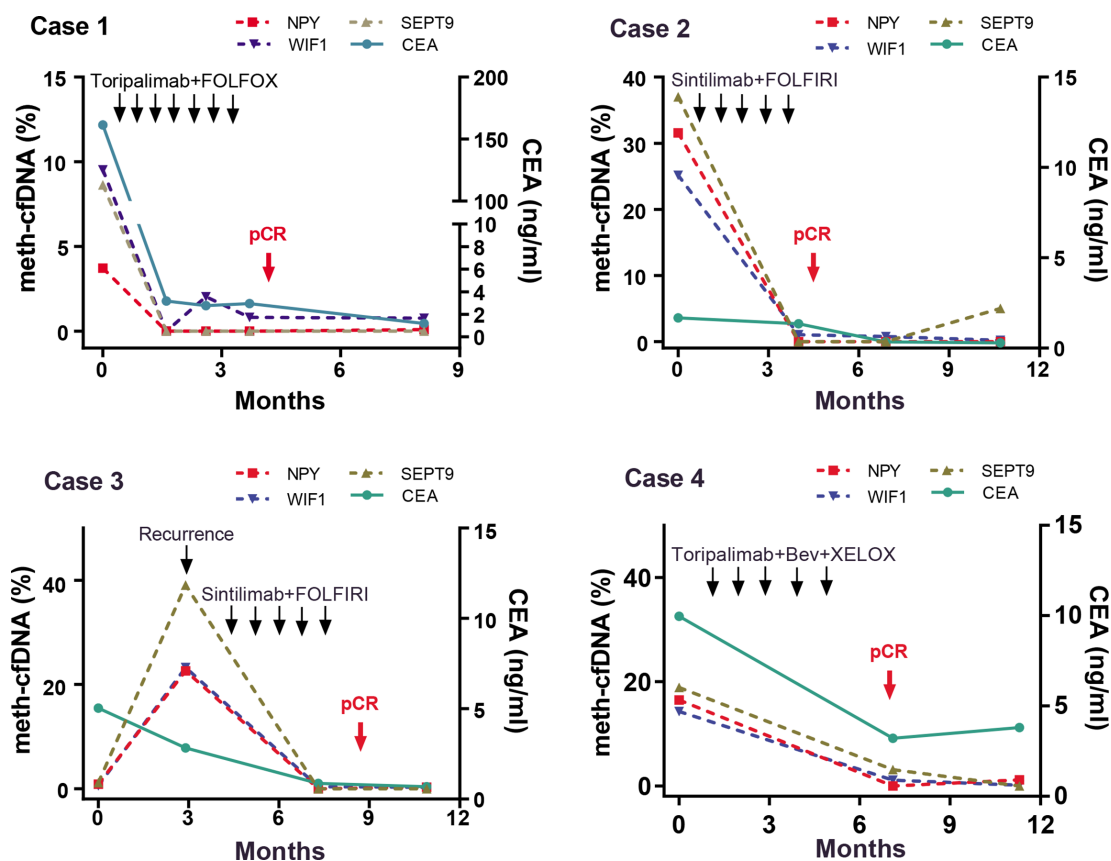

Figure 2 Dynamic changes in serum CEA and circulating NPY/SEPT9/WIF1 DNA methylation of 4 CRLM patients. Bev, bevacizumab; CEA, carcinoembryonic antigen; chemo, chemotherapy; CRLM, colorectal cancer liver metastases; ICI, immune checkpoint inhibitor; meth-cfDNA, circulating cell-free DNA methylation; pCR, pathological complete response.

The overall survival (from initial ICI treatment till the last follow-up) was 14+, 20+, 9+, and 16+months, respectively.

The perioperative ICI-based combination treatment was well tolerated. One patient (case 1) developed grade 3 neutropenia, and another patient (case 3) developed grade 3 anemia. No patient developed immune-related adverse events. All patients underwent radical resection within 1 month after the last cycle of preoperative treatment, and there were no reported surgery-related adverse events.

TMB and gene mutation profiling of *POLE* EDM compared with resected CRLM with other molecular subtypes

The 296 resected CRLM were classified into four molecular subgroups, *POLE* EDM (4, 1.4%), MSI-H (5, 1.7%), *POLE* non-EDM (11, 3.7%), and MSS (276, 93.2%) according to *POLE* and microsatellite status (figure 3A). Demographic and clinicopathological characteristics of the four molecular subgroups were shown in online supplemental table S1. TMB in the four CRLM tumors harboring *POLE* EDM were 453.12, 255.36, 320.64, and 307.20 mutations/Mb, respectively, which was significantly higher than those with MSI-H (median, 313.92 vs 42.24 mutations/Mb, $p < 0.05$, Wilcoxon), *POLE* non-EDM (median, 313.92 vs 4.80 mutations/Mb, $p < 0.001$, Wilcoxon), and MSS tumors (median, 313.92 vs 4.80 mutations/Mb, $p < 0.001$, Wilcoxon). TMB of MSI-H tumors was significantly higher than *POLE* non-EDM (median, 42.24 vs 4.80 mutations/Mb, $p < 0.001$, Wilcoxon) and MSS tumors (median, 42.24 vs 4.80 mutations/Mb, $p < 0.001$, Wilcoxon). TMB was comparable between *POLE* non-EDM and MSS tumors (median, 4.80 vs 4.80 mutations/Mb, $p > 0.05$, Wilcoxon) (figure 3B).

A heatmap of the genetic mutation profiling of the four molecular subgroups was constructed (figure 3C). A large set of mutational genes could be seen in *POLE* EDM tumors. *PI3KCA* (4/4, 100%) and *SMAD 4* (3/4, 75%) mutations were higher in *POLE* EDM tumors compared with other subgroups. DNA damage repair-related genes, including *BRCA2*, *BRCA1*, *ATM*, *ATR*, etc., were generally mutated in *POLE* EDM tumors (all nearly 100%) but were less significant in MSI-H, *POLE* non-EDM or MSS tumors. High *APC* mutations were found across all subgroups (100% in *POLE* EDM tumors and 78.38% among all 296 tumors). Besides, *KRAS* mutations were comparable between *POLE* EDM tumors (50%) and other subgroups (47%). *TP53* mutation was only found in 1 of the 4 (25%) tumors with *POLE* EDM, which was lower than other subgroups (3/5 in MSI-H and 10/11 in *POLE* non-EDM). Interestingly, copy number variation of a series of genes, including *MYC*, *BCL2L1*, *CDKN1B*, *BRCA2*, etc., were common in *POLE* non-EDM and MSS tumors but rarely in *POLE* EDM tumors.

Similar TMB difference and genetic characteristics could be seen in 979 metastatic colorectal tumors with different molecular subtypes in the MSKCC cohort (online supplemental figure S3).

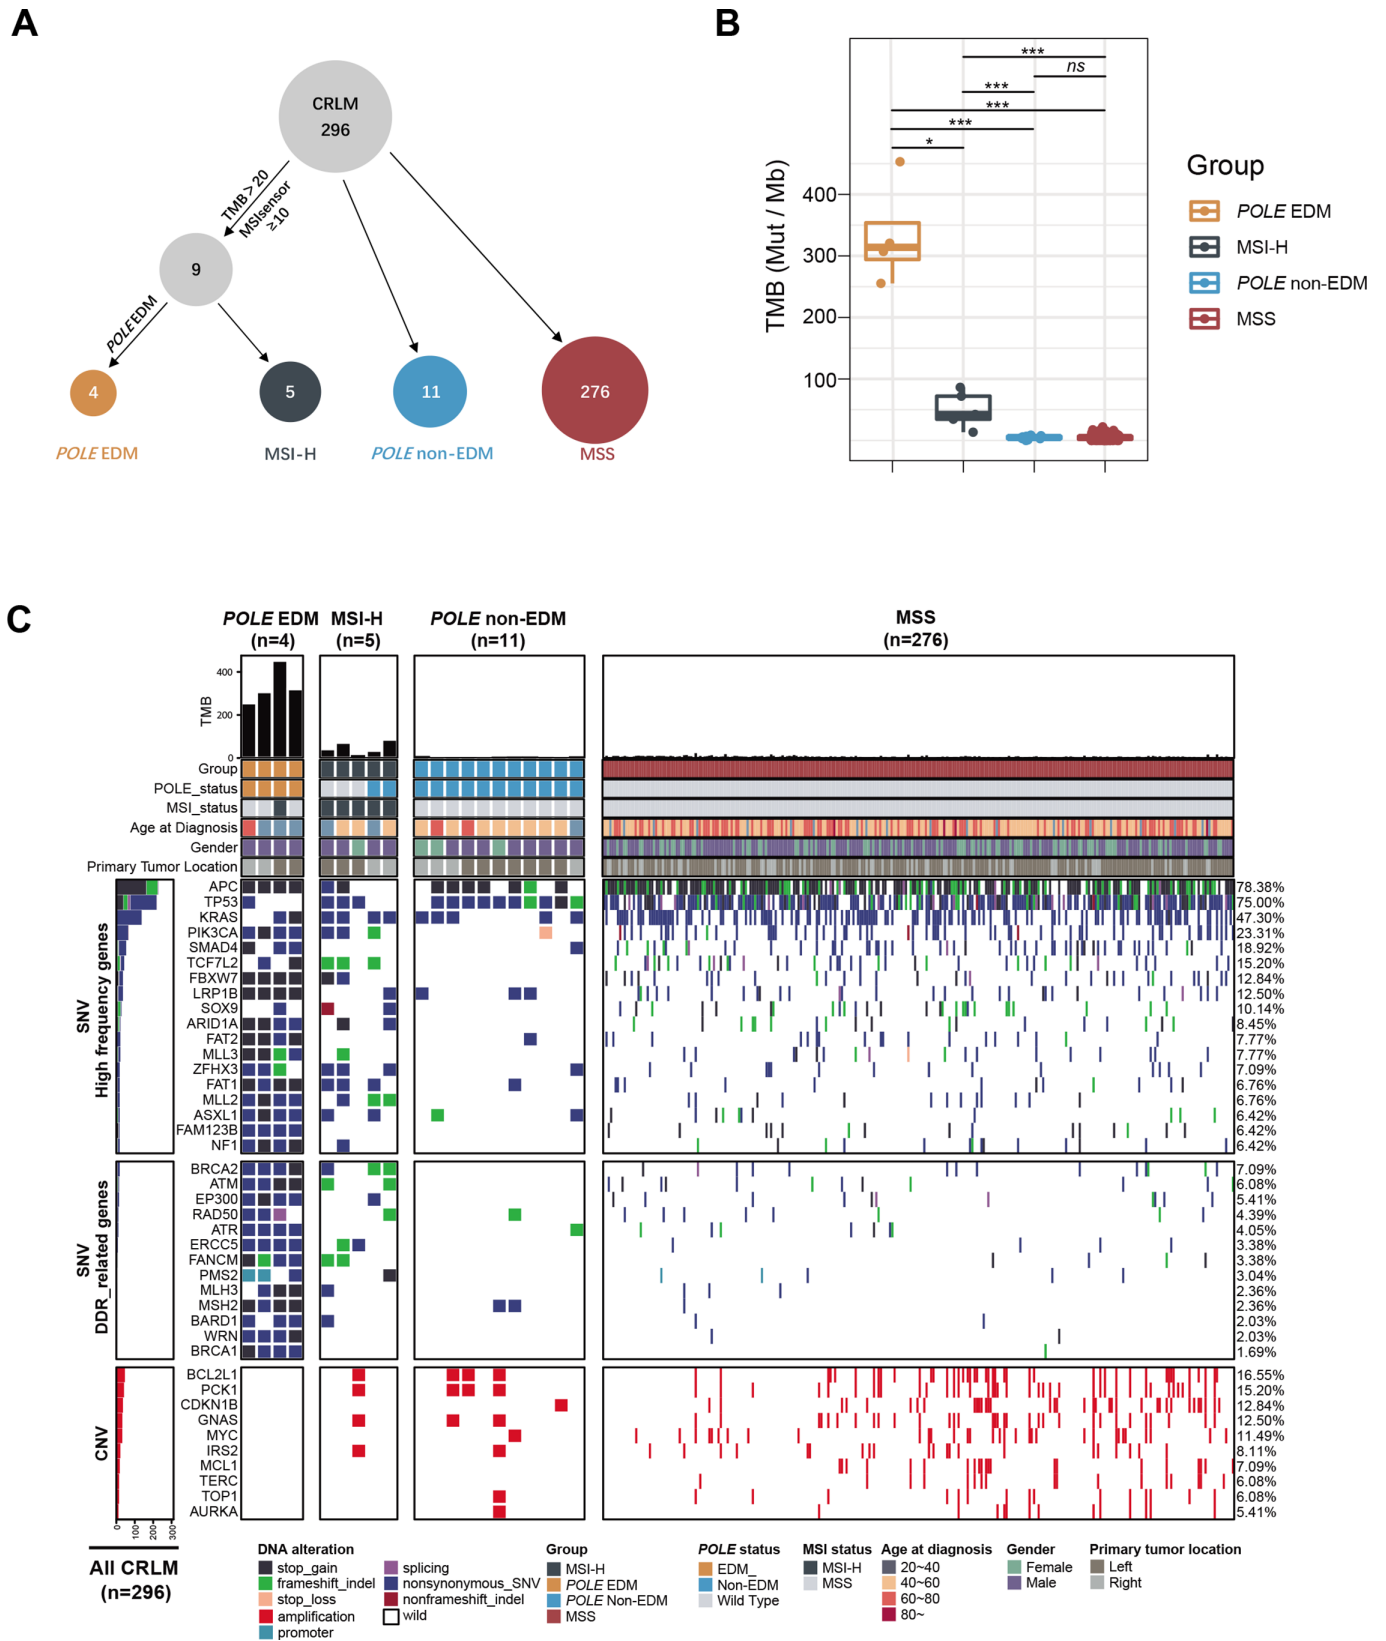

DISCUSSION

The advent of immunotherapy has greatly changed the treatment landscape across a variety of malignancies, including metastatic colorectal cancer. In addition to dMMR and MSI-H, *POLE* gene variants have been suggested as another potential marker for responsiveness to immunotherapy¹⁷ due to their significant association with ultrahigh TMB,¹⁸ which is an effective indicator for response prediction to ICI. The clinical characteristics of patients harboring *POLE* EDM have been reported in different studies.^{19 20} However, due to the rarity of *POLE* EDM in colorectal cancer, limited data reporting the clinical efficacy of ICI in *POLE* EDM patients is available. Here, we present four CRLM patients harboring *POLE* EDM who benefited from ICI-based combination treatment. The radiological overall response rate was 100%, and all four patients (100%) received subsequent complete surgical resection of primary tumor and liver metastases successfully. pCR was achieved both in primary tumor and liver metastases, and the relapse-free status was maintained until the last follow-up.

CRC with pathogenic EDM in the *POLE* gene is characterized by distinct clinical features, tumor microenvironment, and genetic profile.^{9 11 18} Compared with MSS or MSI-H patients, we found that male gender and younger age were more common among patients with *POLE* EDM, which was in line with previous studies.^{11 13} In stage II colorectal cancer, increased CD8 + cytotoxic T lymphocytes and CD45RO+memory immune cells in *POLE* EDM were observed compared with *POLE* wild type or non-EDMs.⁹ Our study also observed a high density of CD3 + and/or CD8 + T lymphocytes, especially in postoperative tumor tissues. At the genetic level, upregulation of a large set of immune-related genes, for example, *CD8A*, *EOMES*, *GZMA*, and *CXCL9*, were observed in *POLE* EDM CRC from the TCGA database.⁹

Both *POLE* EDM and MSI-H lead to ultrahigh TMB in CRC. In the MSKCC cohort, TMB in *POLE* EDM CRC was much higher than in the MSI-H group,¹¹ in line with our results. *POLE* EDM and MSI-H seemed mutually exclusive in metastatic CRC. But in stage II CRC, patients with *POLE* EDMs were more likely to be MSI-H (33.3% vs 11.2%, $p = 0.043$).⁹ In our study, 1 in 4 CRLM patients with *POLE* EDM was MSI-H (25%). PDL1 expression often correlates with a good response to ICIs.²¹ In lung cancer and endometrial cancer, a certain extent of PDL1 expression could be observed in patients with *POLE* EDM.^{22 23} However, PDL1 expression was only weakly positive (CPS 5% in one patient) or negative (3 patients) in the CRLM patients of our study.

Hypermutated tumors, for instance, MSI-H, *POLE* EDM, are sensitive to immunotherapy. KEYNOTE 177⁴ revealed that pembrolizumab alone showed superior efficacy compared with chemotherapy for the treatment of MSI-H advanced colorectal cancer. However, according to RESICT criteria, the proportion of progressed disease in the pembrolizumab arm was 29.4%, which is much higher than 12.3% in the chemotherapy arm, indicating

immunotherapy alone maybe not sufficient for the treatment of some hypermutated colorectal cancer. Additionally, chemotherapeutic drugs may enhance tumor immunogenicity and facilitate antitumor immunity by inducing immunogenic cell death, terms synergistic effect of tumor chemoimmunotherapy.²⁴ Therefore, ICI plus chemotherapy might be a choice for CRLM with *POLE* EDM. On one hand, considering two patients in our cohort were potentially resectable for liver metastases initially which means intensive and effective preoperative treatment was needed to achieve the best tumor radiological regression. On the other hand, ICI had been demonstrated well tolerated when combined with chemotherapy for the treatment of gastrointestinal cancer or thoracic cancer.^{25–27} As a result, the combination of ICI and chemotherapy (with or without bevacizumab) rather than ICI alone was used after *POLE* EDM was detected for these four CRLM patients. Our data showed that the sharp tumor regression and increased lymphocyte infiltration were the result of the combination of ICI and chemotherapy. Whether a single ICI could achieve a similar radiological or pathological response is yet to know. However, we prefer to believe immunotherapy may play a more important role. In fact, two patients progressed after first-line cytotoxic agents and were later rescued with second line agents including ICI, suggesting that like MSI tumors, chemotherapy may not be as efficient in this setting compared with other low TMB CRC.

In our cohort, we observed not-good accordance between radiological and pathological response in these patients, especially in case 3 and case 4, both of whom achieved complete response pathologically but only mild partial response radiologically after anti-PD1 combination treatment. Therefore, to find out robust biomarkers to dynamically monitor the efficacy of treatment is of great importance. DNA methylation is an epigenetic regulator of gene expression and cfDNA-bearing cancer-specific methylation patterns have been investigated as feasible biomarkers in diagnostic, prognostic, as well as treatment response monitoring of cancer. Bhangu *et al* found that serial measurements of CRC-associated methylation markers could be a particularly valuable tool for early response assessment in patients receiving neoadjuvant chemotherapy for CRLM.²⁸ In our cohort, NPY/SEPT9/WIF1 methylation dynamics in cfDNA seemed to be correlated well with actual tumor burden changes since NPY/SEPT9/WIF1 meth-cfDNA decreased from a high level at baseline to a nearly undetectable level after treatment in all four patients. NPY/SEPT9/WIF1 meth-cfDNA was also more sensitive than the traditional CRC tumor marker, CEA, in this study. NPY/SEPT9/WIF1 meth-cfDNA clearance could become a potential indicator of pCR in CRLM patients with *POLE* EDM receiving anti-PD1 treatment, even if a radiological complete response is not reached. Similar to the ‘watch and wait’ strategy in locally advanced rectal cancer who achieved pCR after chemoradiation,²⁹ we think that delayed surgical intervention might be a choice for CRLM patients with *POLE*

EDM who could reach pCR after ICI treatment, especially considering the extensive and complexity of surgical resection for both primary colorectal cancer and liver metastases.

Based on the excellent clinical efficacy of immunotherapy from the present case series and previous case report,³⁰ we suggest that the complete sequencing of *POLE* exonuclease domains by NGS or PCR is recommended in clinical practice before the treatment of metastatic colorectal cancer. One limitation of this study is the small number of patients due to the rarity of *POLE* EDM in colorectal cancer. As a result, findings from this study should be interpreted with caution and warrant further verification in such patients in the future.
