Background: Acute application of decanoic acid (DA) in vivo suppresses the excitability of spinal trigeminal nucleus caudalis (SpVc) wide dynamic range (WDR) neurons associated with the short-term mechanical hypoalgesia via muscarinic M_2 receptor signaling; however, the effect of DA on nociceptive trigeminal ganglion (TG) and SpVc nociceptive-specific (NS) neuronal excitability under in vivo conditions remains to be determined. The present study investigated whether this effect could be observed in naive rats.

Results: Extracellular single-unit recordings were made from TG and SpVc NS neurons of pentobarbital-anesthetized rats in response to orofacial noxious mechanical stimuli. DA inhibited the mean firing frequency of both TG and SpVc NS neurons, reaching a maximum inhibition of discharge frequency within 1–5 minutes and reversing after approximately 10-minutes; however, this DA-induced suppression of SpVc NS neuronal firing frequency did not occur in rats administered with methoctramine intravenously prior to stimulation.

Conclusion: This in vivo study indicated that firing of TG and SpVc NS neurons induced by mechanical hypoalgesia through peripheral M_2 receptors could be inhibited by acutely administered DA, implicating the potential of DA in the future treatment of trigeminal pain.

Perspective: This article presents that the acute DA application suppresses the excitability of TG and SpVc NS neurons associated with mechanical hypoalgesia via peripheral M_2 receptor signaling, supporting DA as a potential therapeutic agent in complementary and alternative medicine for the attenuation of nociception.

Introduction

Nociceptive sensory data derived from trigeminal ganglion (TG)-innervated orofacial regions that connect spinal trigeminal nucleus caudalis (SpVc) neurons and the upper cervical (C1–C2) dorsal horn provide critical conduits for trigeminal nociceptive pain associated with inflammation and tissue injury.[1–3] SpVc nociceptive neurons were classified as nociceptive specific (NS) and wide dynamic range (WDR) based on their sensitivity to mechanical stimulation applied to the orofacial area such as facial skin. WDR neurons responded to both noxious and nonnoxious stimulations.[3] Since graded noxious stimuli applied to receptive field produce increased firing frequency of SpVc WDR neurons in proportion to stimulus intensity, it can be assumed that WDR neurons play an important role in encoding stimulus intensity. However, NS neurons respond only to noxious stimulation of receptive field and therefore play an important

role in encoding noxious stimulus localization via nociceptive TG neurons to higher centers in the central nervous system.

Complementary and alternative medicine (CAM), such as herbal medicines and acupuncture, has been trialed for treating persistent clinical chronic pain.[4–6] For example, the potential effects of diet and dietary supplementation on conditions associated with pain have been the focus of considerable research.[7–9] Indeed, polyphenolic compounds (eg, resveratrol and chlorogenic acid) and fatty acids (eg, decanoic acid [DA] and docosahexaenoic acid) modulate the neuronal excitability of the peripheral nerves, including those of the sensory system, via various voltage-dependent ionic channels, ligand-gated channels, and neurotransmitter receptors.[10–13] As previously discussed, DA displays several potential biological activities, including the antagonism of muscarinic acetylcholine receptors (mAchRs).[14] Indeed, we previously showed that DA applied acutely as an ointment induces mechanical hypoalgesia, predominantly by limiting the SpVc WDR neuronal excitability via peripheral acetylcholine muscarinic 2 (M_2) receptors, suggesting a role of this fatty acid in CAM for trigeminal nociceptive pain present without inflammation or neuropathy.[11] Thus, the present study further investigated how a similar acute treatment with DA affects TG and SpVc NS neuronal activities associated with hypoalgesia in naive rats.

Methods

The Animal Use and Care Committee of Azabu University approved the present study. The protocols also adhered to the ethical guidelines of the International Association for the Study of Pain;[15] specifically, we used as few animals as possible to achieve the target results and minimized their suffering wherever possible.

Local, cutaneous application of DA as an ointment

DA (molecular weight [MW]=172.26 kDa) is a saturated, medium-chain fatty acid with a 10-carbon backbone ($C_{10}H_{20}O_2$) and is lipophilic (log P=4.09). Therefore, we formulated an ointment for in vivo application of DA (Patent number: P2013-139421A, Japan), as described and defined previously.[11]

Electrophysiological experiments for single-unit recording of neurons

Electrophysiological recordings were conducted on 26 adult male Wistar rats weighing 230–310 g (18 rats: SpVc NS neurons; 8 rats: TG neurons), as previously described.[11] In brief,

after anesthesia and maintenance with pentobarbital sodium through a cannula into the jugular veins, animals were placed in a stereotaxic apparatus for extracellular activity recordings of single SpVc neurons, according to the coordinates demonstrated by Paxinos and Watson,[16] using a glass micropipette filled with 2% pontamine sky blue and 0.5 M sodium acetate.[11,17] For recordings of single TG neurons, the rats underwent a craniotomy and hemispherectomy to expose the trigeminal ganglia, and the activity was recorded from the left side of the neurons, as described for the SpVc units.[18,19] All neuronal recordings were amplified (DAM80; World Precision Instruments, Sarasota, FL, USA), filtered (0.3–10 KHz), monitored with an oscilloscope (SS-7672; Iwatsu, Tokyo Japan), and then recorded for offline analysis using Power Lab and Chart 5 software (ADInstruments Ltd, Oxford, UK), as described previously.[11,17] During all recordings, we monitored anesthesia state of the rats based on the absence of corneal reflex and response to paw pinching as well as rectal temperatures, and wound margins were continuously covered with a local anesthetic, 2% lidocaine.

Experimental protocols

We conducted extracellular recordings of SpVc NS and TG neuronal activities as previously described.[11,17] Briefly, we immediately identified the receptive field on the left side of the orofacial skin (whisker pad) using mechanical stimulation without sensitizing the peripheral receptors. We then applied noxious pinch and mechanical stimulation to the whisker pad using von Frey hairs (>15 g: 15, 26, and 60 g) and forceps, indentified the responsive SpVc WDR neurons, and tested for spontaneous discharge. Subsequently, we determined the threshold for mechanical nociception using nonnoxious and noxious stimulation with von Frey hairs (4, 6, 10, 15, 26, and 60 g) applied at 5-second intervals. The mechanical receptive field of neurons was mapped by probing the facial skin with von Frey hairs and then outlined on a life-sized drawing of a rat on tracing paper. Mechanically induced TG and SpVc NS neuronal discharges were quantified, and spontaneous discharge frequencies were determined over 2–5 minutes, with no discharge indicating a "silent" neuron. We then compared the mean neuronal firing rates following mechanical stimulation before and after drug administration and generated poststimulus histograms (bin=100 ms). SpVc NS neuronal activity following DA and vehicle treatments was evaluated during the peak effect and recovery period at 1, 3, 10, and 20 minutes. In addition, we assessed DA-induced changes in firing of the mechanically stimulated SpVc WDR neurons based on the effect of pretreatment with an M_2 mAchR-specific antagonist, methoctramine (1 mM;

Sigma-Aldrich Co., St Louis, MO, USA) 10 minutes before the DA treatment (n=6).[11]

Identification of recording sites for SpVc NS neurons

At the end of the recording sessions, rats were deeply anesthetized, and anodal DC currents were passed through the recording micropipettes (30 µA, 5 minutes), followed by transcardial perfusion with 10% formalin in saline. Coronal sections were cut frozen (30-µm thickness) for H&E staining. Recording sites were identified from the blue spots, and electrode tracks were constructed based on the micromanipulator readings.

Data analyses

Values are expressed as mean±standard error of the mean. Statistical analyses were performed using one-way repeated

measures ANOVA, followed by Tukey–Kramer/Dunnett tests (post hoc test) for behavioral and electrophysiological data. $P<0.05$ was considered statistically significant.

Results

General properties of TG neurons responding to mechanical stimulation of orofacial skin

Extracellular single-unit activity was recorded from eight neurons in the trigeminal ganglia. The TG neurons responding to noxious mechanical stimulation exhibited a somatic receptive field in the orofacial area (mainly whisker pad; Figure 1A), as described previously.[18,19] No units exhibited spontaneous discharges. As shown in Figure 1B, recording sites were found in the mandibular branches, as described previously,[20] and typical examples of nociceptive TG neuronal unit responses are shown in Figure 1C. Graded mechanical

stimulation was applied to the most sensitive area of the receptive field, which exhibited increased firing frequency of TG neurons in proportion to stimulus intensity (Figure 1D). The mean mechanical stimulation-induced spike threshold was 11.5±2.8 g (n=6). Every neuron recorded belonged to the category of NS neurons.

Effect of DA on the excitability of TG neurons responding to nonnoxious and noxious mechanical stimulation

Figure 1E shows typical examples of DA treatment effects on the excitability of TG neurons in response to noxious mechanical and pinch stimulation, as described in earlier studies.[11] Briefly, these effects constituted inhibition of TG neuronal activity 1–5 minutes after DA treatment with a return to control levels in approximately 10 minutes for both modes of noxious stimulations. As indicated in Figure 1F, the mean firing rates of stimulated TG neurons decreased significantly after DA treatment, compared with rates before DA treatment (15 g stimulus, 18.1±1.3 vs 7.3±0.5 Hz, F=10.3, n=8; 60 g stimulus, 35.2±2.2 vs 12.1±0.6 Hz, F=4.1, n=6; and pinch stimulus, 46.1±2.2 vs 18.5±1.1 Hz, F=7.2, n=8, before vs after DA for 3 minutes, respectively). No significant changes were observed in the mean receptive field size after DA administration (11.5±0.1 vs 10.5±0.3

mm^2, before vs after DA, respectively) or in the spontaneous firing rate. Vehicle treatment had no significant effect on either spontaneous or evoked (noxious mechanical and pinch stimulation) activity of the TG neurons (n=4; data not shown).

General properties of SpVc NS neurons responding to mechanical stimulation of orofacial skin

Next, we observed inhibited firing in all 10 SpVc NS neurons tested for their responses to DA following nonnoxious and noxious mechanical stimulations of the whisker pad. Of these, three neurons did not recover their control levels of activity, leaving seven SpVc NS neurons for further analyses. Confirming our previous findings, these responsive neurons displayed a somatic receptive field in the buccal region of the orofacial skin (Figure 2A), with recording sites mainly distributed in the maxillary and mandibular branches in layers I–II (n=7) and IV (n=3) of the SpVc (obex, –1.0 to –2.0 mm; Figure 2B).[11] The inset in Figure 2B represents the histological confirmation conducted for each such recording site. Finally, we identified the most sensitive area of the receptive field with respect to the stimulus-proportional increase in firing frequency of SpVc NS neurons induced by the graded mechanical stimulation (Figure 2C).

Effect of DA on the excitability of SpVc NS neurons responding to noxious mechanical stimulation

Figure 3 further represents the typical DA effects on SpVc NS neuronal excitability in response to noxious stimulation, with inhibition of the firing obvious from 1 to 5 minutes after DA treatment, and activity returning to control levels within 10 minutes. The mean SpVc NS neuronal firing rates induced by both mechanical and pinch stimulations decreased significantly after DA treatment (15 g stimulus, 15.7±1.5 vs

5.5±0.7 Hz, F=13.6, n=7; 60 g stimulus, 36.4±2.1 vs 10.9±1.8 Hz, F=35.0, n=7; and pinch stimulus, 57.1±3.3 vs 19.4±2.3 Hz, F=37.7, n=7, before DA treatment vs 3 minutes after DA treatment, respectively), but there were no significant changes in either mean receptive field size (12.5±0.1 vs 13.9±0.3 mm^2, before vs after DA, respectively) or spontaneous firing. Vehicle treatment had no significant effects on the activity of SpVc NS neurons (n=2; data not shown).

Pretreatment with M$_2$ mAchR antagonist attenuates the DA-induced inhibition of SpVc NS neurons responding to noxious stimulation

Pretreatment with the M$_2$ mAchR antagonist methoctramine (1 mM, intravenously [iv]) significantly inhibited the DA-induced suppression of SpVc NS neuronal firing in response to noxious stimulation (n=6; Figure 4; 15 g, 9.1±3.3 vs 24.5±2.3 Hz, F=6.9, n=6; 26 g, 12.4±2.0 vs 33.1±2.5 Hz, F=9.2, n=6; 60 g, 19.1±2.6 vs 46.2±5.1, F=15.2, n=6; and pinch, 25.2±4.6 vs 52.4±5.2 Hz, F=15.5, n=6, for DA vs DA+methoctramine, respectively).

Comparison of DA-induced inhibition between SpVc NS and WDR neuronal activity

Finally, we compared the relative inhibitory effect of DA on neuronal discharges of SpVc NS and WDR neurons using our published data.[11] Although we previously observed a tendency that the magnitude of inhibition of SpVc NS neurons was stronger than those of SpVc WDR neurons, the mean magnitude of inhibition by DA of discharge frequency was not significantly greater for NS neurons compared to WDR neuron (NS vs WDR: 15 g, 63.5%±5.8% vs 55.0%±6.5%; 26 g, 61.7%±5.7% vs 51.0%±5.6%; 60 g, 67.6%±6.1% vs 49.0%±8.6%; and pinch, 63.1%±4.7% vs 53.0%±7.0%).

Discussion
Inhibition of SpVc NS neuronal excitability by DA

Noxious sensory information in the area innervating the trigeminal nerve is relayed from trigeminal primary afferents (TG neurons) to second-order neurons in the SpVc and the C1–C2 dorsal horn.[1–3] Two types of nociceptive neurons exist in the SpVc based on their sensitivity to mechanical stimulation applied to the orofacial area, such as facial skin.[3] Basically, NS neurons are located in the superficial layer (laminae I–II) and respond only to noxious stimulation

(high-threshold mechanical stimulation) of receptive fields, suggesting that NS neurons transmit noxious information of stimulus localization to the higher centers.[2,3] Pain is known to have very complicated aspects, namely sensory-discriminative, motivational, and affective aspects.[21] The sensory discriminative aspect of pain is analogous to nonnoxious sensation and thought to be involved in the discrimination of pain features such as location, intensity, and quality (via the lateral pain pathway).[3] On the other hand, the motivational and affective aspects of pain are probably related to emotional and autonomic responses due to long-lasting, intense noxious stimuli (via the medial pain pathway).[3] Indeed, many of the central projection neurons, such as NS neurons in the superficial layer, target for the parabrachial nucleus (PBN),[22] which receives input from the NS neurons in the superficial dorsal horn and projects it to the forebrain areas such as the amygdala and hypothalamus.[23] Through these connections, the spinoparabrachial pathway is likely to be involved in emotional (involving aversive) and autonomic components of pain. Therefore, it can be assumed that NS neurons are important for both localizing noxious stimulation and affecting emotional and autonomic comportments.

The present study confirmed two key findings described by us previously.[11] First, we observed rapidly inhibited mechanical stimulation-induced firing of SpVc NS neurons by local application of DA, and second, the DA-induced effect was similar in both time course and magnitude of inhibition for SpVc NS and WDR neurons. The sensory discriminative aspect of pain is thought to be involved in discriminating pain features, such as location, intensity, and quality, while the motivational and affective aspects of pain relate to emotional and autonomic responses due to long-lasting, intense noxious stimuli.[21] The aspect is considered to be a feature of persistent pain associated, for example, with chronic inflammation or peripheral nerve injury. In the present study, we confirmed the previous observation that DA induced short-term suppression of excitability in both NS neurons and SpVc WDR neurons.[11] Taken together, therefore, our findings suggested that DA inhibits not only sensory discriminative aspects of pain but also motivational and affective aspects. Further study is needed to elucidate this intriguing possibility.

Mechanism underlying DA-induced hypoalgesia

We previously showed in vivo that DA-induced motor activity is reversibly abolished by a muscarinic antagonist, implicating DA as an mAchR agonist.[14] Bernardini et al[24] also demonstrated using a rat skin-nerve preparation that M$_2$
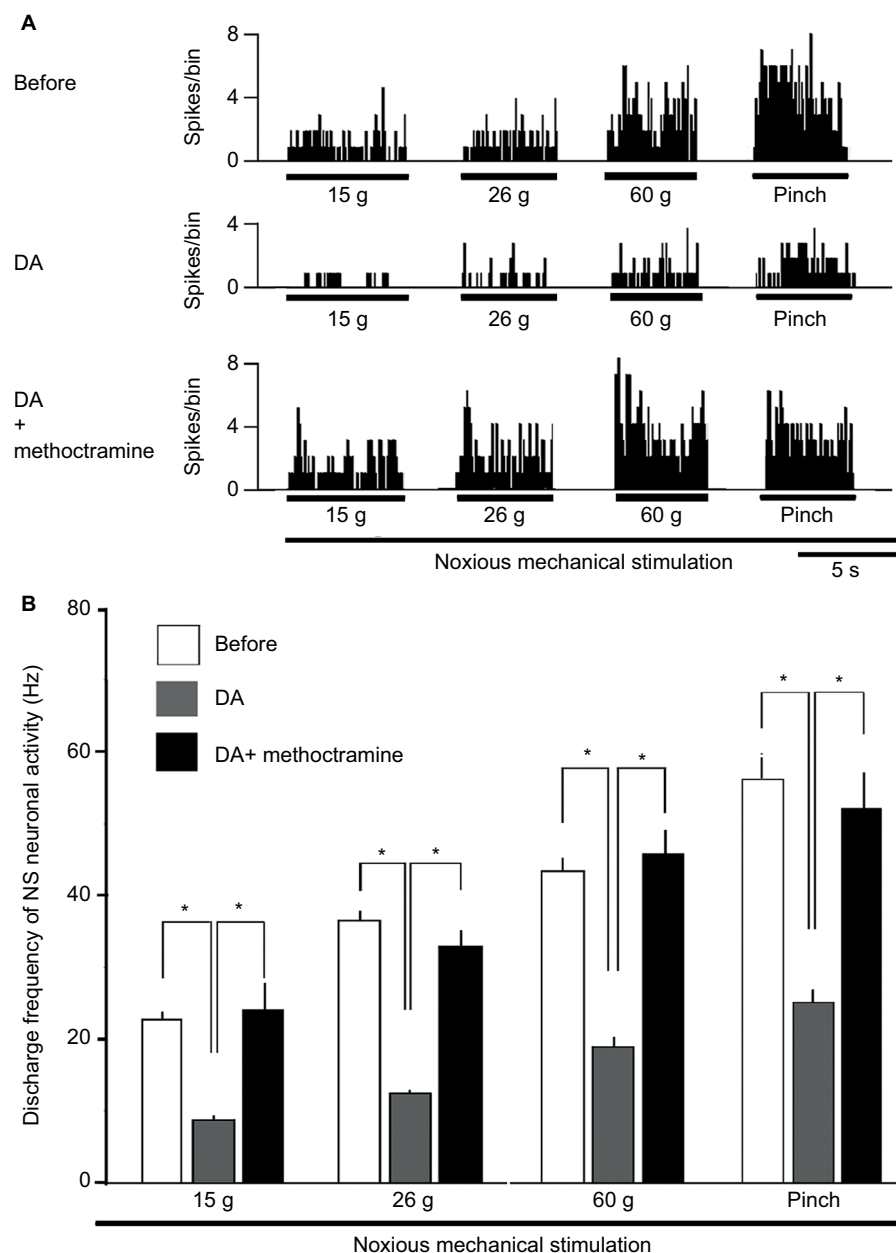

A

mAchRs desensitize the peripheral terminal of C-nociceptors, possibly via the low-threshold, voltage-operated K⁺ channels, which buildup a hyperpolarization force.[25] Noguchi et al[11] also demonstrated that most small-diameter TG neurons innervating facial skin expressed M₂ mAchR immunoreactivity (92%), and the remaining neurons were medium-diameter TG neurons (7%), of which 53% also labeled positive for the neurofilament protein-200 (NF-200) myelinated fiber marker, suggesting Aδ-type TG neurons. On this background, the DA

effects demonstrated herein, together with the result of M₂ receptor antagonism, indicate that the acute administration of DA induces short-term mechanical hypoalgesia predominantly by suppressing SpVc WDR neurons via peripheral M₂ receptor signaling in Aδ- and C-type TG neurons.

Taken together, our results combined with the previous study[11] strengthen the case for a possible mechanism underlying DA treatment-induced hypoalgesia (Figure 5), in that when noxious mechanical stimulation is applied to

the skin, mechanosensitive ion channels open (eg, transient receptor potential [TRP] channel family, such as TRPA1),[26] activating the generator potential (depolarization). This depolarization further opens voltage-dependent sodium and potassium channels, generating action potentials, which are then discharged through trigeminal primary afferent fibers (Aδ- and C-fibers) to the central terminal in nociceptive SpVc neurons. When DA is applied (including as an original ointment) to the surface of skin, it acts on a mAchR agonist.[14] Consequently, M$_2$ mAchRs have a reduced influence on the peripheral terminal of primary nociceptive neurons,[11] supporting a role in affecting low-threshold voltage-operated K$^+$ channels and the attendant hyperpolarization force.[25] This effect might in turn decrease the firing frequency of action

potentials in the nociceptive trigeminal nerve terminals and inhibit the conduction of pain signal to the SpVc and higher center for lateral and medial pain control (hypoalgesia).

Functional significance for DA treatment-induced hypoalgesia

CAM, such as herbal medicines and acupuncture, has been used for the treatment of clinical pain.[4–6] Since polyphenolic compounds and fatty acids modulate the neuronal excitability of peripheral nerves, including the sensory system, via various voltage-dependent ionic channels, ligand-gated channels, and neurotransmitter receptors,[10–13] it can be assumed that diet and dietary supplementation can potentially affect conditions associated with pain.[7–9] Thus, our results suggest that dietary

Figure 5 A possible mechanism of underlying DA treatment-induced short-term hypoalgesia.
Notes: When noxious mechanical stimulation is applied to the skin, mechanosensitive ion channels open (eg, TRP channel family, such as TRPA1), activating the generator potential (depolarization). This depolarization further opens voltage-dependent sodium and potassium channels, generating action potentials, which are in turn discharged through primary afferent fibers (Aδ- and C-fibers) to the central terminal of nociceptive neurons in the SpVc. DA (including original ointment) application to the skin acts as an mAchR agonist.[14] M$_2$ mAchRs exert an inhibitory or desensitizing influence on the peripheral terminal of nociceptive neurons. This desensitization can be explained by the fact that, apart from lowering the intracellular cAMP concentration, M$_2$ mAchRs also affect low-threshold voltage-operated K$^+$ (kv) channels that buildup a hyperpolarization force.[25] This effect might decrease the firing frequency of action potentials in the nociceptive nerve terminals and inhibit the conduction of pain signal to the SpVc and higher center for lateral and medial pain control (hypoalgesia).

constituents such as DA with resveratrol, chlorogenic acid, and docosahexaenoic acids might additively contribute to the development of analgesic drugs with fewer and less severe toxic side effects for treating pathological pain, including orofacial pain. In this study, we reconfirmed the short-term hypoalgesic effect of DA application in an ointment form onto natural cutaneous tissue.[11] Therefore, it can be speculated that such an ointment might effectively reduce clinical pain, such as injection-related pain during blood sampling; however, further study is needed to clarify this proposal.

Conclusion

The present study confirmed the inhibitory effect of DA on TG and SpVc NS neuronal excitability induced by short-term mechanical hypoalgesia and implicated peripheral M_2 receptor signaling in mediating the DA effect. These extended in vivo findings support the potential role of DA in CAM for attenuating trigeminal nociception in the absence of confounding conditions.
