**Abstract.** In order to explore the optimal timing for initiating cytorreduction chemotherapy following all-trans retinoic acid plus arsenic trioxide administration, 58 newly diagnosed patients with acute promyelocytic leukemia (APL) with low-intermediate mortality risk were retrospectively analyzed. During induction treatment, white blood cell (WBC) count  $>4 \times 10^9/l$  and multiplication rate of WBC  $<3$  days were defined as rapid WBC multiplication. Patients were divided into two groups: With or without rapid WBC multiplication. Comparison between the two groups revealed that the incidence of differentiation syndrome (DS) (48.1% vs. 6.5%;  $P < 0.001$ ), grade 3-4 bleeding (34.8% vs. 6.5%;  $P = 0.022$ ) and peak WBC count ( $30.4 \pm 20.0 \times 10^9/l$  vs.  $8.67 \pm 5.4 \times 10^9/l$ ;  $P < 0.001$ ) were significantly higher in the group with rapid WBC multiplication compared with in the group without rapid WBC multiplication. No significant differences were observed in bone marrow depression, infection, complete remission (CR) rate, time to achieve CR and early mortality rate between the two groups. Multivariate analysis revealed that WBC

count at chemotherapy initiation was an independent risk factor for the occurrence of DS ( $P = 0.040$ ). Peak WBC count and rapid WBC multiplication were significantly associated with grade 3-4 bleeding ( $P = 0.019$  and  $P = 0.002$ , respectively). Hence, WBC count at chemotherapy initiation along with its multiplication rate may direct the timing of cytorreduction chemotherapy during induction treatment in newly diagnosed APL with low-intermediate risk.

## Introduction

All-trans retinoic acid (ATRA) and arsenic trioxide (ATO) are two basic drugs for induction treatment for newly diagnosed acute promyelocytic leukemia (APL). Based on numerous clinical trials (1,2), the *National Comprehensive Cancer Network* (NCCN) guideline recommends ATRA combined with ATO as the standard induction treatment for de novo APL with low risk [white blood cell (WBC) count  $<10 \times 10^9/l$  (3)]. Only if there are any contraindications to arsenic, ATRA combined with idarubicin could be considered (4-6). Chinese APL guideline also recommends ATRA combined with ATO as basic treatment for induction therapy for de novo APL (7). Anthracyclines or other cytorreduction chemotherapy could be chosen if WBC count is  $>10 \times 10^9/l$ . After administration of ATRA and ATO, WBC count will typically rise and may lead to differentiation syndrome (DS). Cytorreduction chemotherapy may partially prevent or control the risks of DS. However, no guidelines give specific suggestions about when and how to initiate cytorreduction chemotherapy. Our previous research indicated that it was better to initiate cytorreduction chemotherapy when WBC count was between  $4 \times 10^9/l$  and  $15 \times 10^9/l$  during induction treatment for APL with low-intermediate risk (8). It is difficult for clinicians to decide to use chemotherapy when WBC count is not very high. However, the WBC count occasionally multiplies and exceeds  $15 \times 10^9/l$  very rapidly before clinicians can make a decision. To assess the appropriate time to initiate cytorreduction therapy during induction treatment, static WBC count may not be universally satisfactory. Hence, this study was designed to explore the relationship between the

multiplication rate of WBC count and clinical effects during ATRA plus ATO-based induction treatment for patients with low-intermediate risk APL.

## Patients and methods

**Patients.** Between January 2015 and December 2020, a total of 92 newly diagnosed patients were admitted to our hematology department. Of these, 60 patients were categorized into the low-intermediate risk group, and the remaining patients were categorized into the high risk group, based on Sanz's risk stratification model for survival prediction (9). All 58 patients (34 males and 24 females), with a median age of 34 years (range 17-71 years) with low-intermediate risk, who had complete clinical data, were retrospectively enrolled in this study. Disease diagnosis was confirmed by bone marrow aspiration, chromosome karyotyping analysis, fluorescence *in situ* hybridization analysis and polymerase chain reaction. Informed consent prior to and regarding the treatment protocol was obtained from all patients analyzed in the present study.

**Treatments.** When a diagnosis of APL was suspected, ATRA (20 mg/m<sup>2</sup>/day) was administered at the earliest, until complete remission (CR) was achieved. All 58 patients received ATRA and ATO-based induction treatment. If the WBC count increased, cytotoxic agents-based chemotherapy was initiated based on the clinician's decision in order to reduce leukemia cells and prevent risks of DS. A total of 19 cases received idarubicin (8 mg/m<sup>2</sup>/day on days 1-3), 32 cases received daunorubicin (45 mg/m<sup>2</sup>/day on days 1-3), two cases received daunorubicin (45 mg/m<sup>2</sup>/day on days 1-3) combined with cytarabine (100 mg/m<sup>2</sup>/day on days 1-7), and five cases received only hydroxyurea (2.0-3.0 g/day, adjusted according to blood cells). Blood product support was applied to maintain platelet (PLT) level  $\geq 30 \times 10^9/l$ , hemoglobin level  $\geq 70$  g/l and plasma fibrinogen level  $\geq 1.5$  g/l. All adverse events related to treatments, including bone marrow depression, infection and bleeding, were graded according to the National Cancer Institute Common Terminology Criteria for Adverse Events version 4.03 (10).

**Definitions and groups.** DS was diagnosed based on the incidence of at least two of the following clinical features: Unexplained fever, acute respiratory distress with interstitial pulmonary infiltrates, acute renal failure, weight gain >5 kg, unexplained hypotension, and pleuropericardial effusion (11). Prevention strategies included dexamethasone (10 mg q12h), and discontinuation of ATRA and ATO. All 58 patients were categorized according to Sanz's risk stratification score (9) as low risk (WBC count  $< 10.0 \times 10^9/l$  and PLT  $\geq 40.0 \times 10^9/l$  at diagnosis) and intermediate risk (WBC count  $< 10 \times 10^9/l$  and PLT  $< 40.0 \times 10^9/l$ ). CR was defined as the presence of <5% blast cells in bone marrow aspirates, PLT  $> 100 \times 10^9/l$  and no juvenile cells in peripheral blood according to the criteria established by the US National Cancer Institute (12). Early mortality was defined as fatality during induction treatment from the first day of hospitalization. Eastern Cooperative Oncology Group (ECOG) performance status score (0-4 score) was applied to investigate the patient's physical status prior to chemotherapy (13). WBC count  $> 4 \times 10^9/l$  and WBC multiplication

time  $< 3$  days was defined as rapid WBC multiplication. Table I presents a comparison of the baseline clinical and laboratory parameters of the groups with rapid WBC multiplication and without rapid WBC multiplication.

**Statistical analysis.** Statistical analysis was performed with SPSS v.22.0 software (SPSS Inc.). All data were collected in December 2020. Clinical features are presented as percentages (%) for categorical variables, and as mean values  $\pm$  standard deviation for normally distributed continuous variables. The  $\chi^2$  test was used to analyze the significance of differences in the distribution of categorical variables between the patient subsets, and the SNK method and Bonferroni's correction were used to compare the two groups. The unpaired Student's t-test or Mann-Whitney U test was used to analyze the significance of differences in the distributions of continuous parametric variables and ranked variables. Multivariate analysis was performed using a binary logistic regression model. WBC count at diagnosis, WBC count at chemotherapy initiation, peak WBC count, and with or without rapid WBC multiplication were considered in the multivariate analysis to evaluate their effects on DS, early mortality and grade 3-4 bleeding.  $P < 0.05$  was considered to indicate statistical significance.

## Results

**Comparisons of clinical effects between patients with and without rapid WBC multiplication.** Comparison of the baseline features, clinical and laboratory parameters is shown in Table I. No significant differences were found in age, gender and ECOG score between the two groups. WBC count at diagnosis was slightly higher in the group with rapid WBC multiplication ( $2.14 \pm 1.66 \times 10^9/l$  vs.  $3.82 \pm 2.98 \times 10^9/l$ ,  $P = 0.013$ ). There was no difference between the two groups in Sanz's risk stratification ( $P = 0.121$ ). Biochemical tests showed no differences in uric acid, albumin and creatine levels in patients with or without rapid WBC multiplication. Coagulation functions including activated partial thromboplastin, prothrombin time, fibrinogen and D-dimer level were similar in the two groups.

As depicted in Table II, the incidence of DS was higher (48.1 vs. 6.5%,  $P = 0.000$ ), grade 3-4 bleeding was more frequent (34.8 vs. 6.5%,  $P = 0.022$ ), and peak WBC count was higher ( $30.4 \pm 20.0 \times 10^9/l$  vs.  $8.67 \pm 5.4 \times 10^9/l$ ,  $P = 0.000$ ) in the rapid WBC multiplication group. There were no differences in bone marrow depression, infection, CR rate, time to achieve CR and early mortality rate between the two groups.

**Multivariate associations.** To further evaluate the effects of dynamic changes of WBC count during induction treatment on DS, early mortality and bleeding events, a binary logistic regression model was used. The results of multivariate analysis revealed that WBC count at chemotherapy initiation was an independent risk factor for the occurrence of DS [ $P = 0.040$ , odds ratio (OR) = 1.0216, 95% confidence interval (CI) = 1.009-1.465]. Peak WBC count and rapid WBC multiplication were significantly related to grade 3-4 bleeding ( $P = 0.019$ , OR = 0.773, 95% CI = 0.623-0.959;  $P = 0.002$ , OR = 99.567, 95% CI = 5.738-1727.726). However, WBC count at

diagnosis, WBC count at chemotherapy initiation, peak WBC count and rapid WBC multiplication were not independent risk factors for early mortality (Table III).

## Discussion

European Leukemia Net updated the recommendations for management of APL in 2019 (14). For non-high-risk APL patients (WBC ≤10x10<sup>9</sup>/l), either ATRA plus ATO without chemotherapy or standard ATRA-idarubicin therapy were recommended as induction treatment, which was consistent with NCCN guidelines (3). In both guidelines, when and how to use cytorreduction therapy during ATRA plus ATO-based induction treatment was not discussed. However, the risks of DS may increase with the increase of WBC count, which may lead to other serious side effects. Hence, a randomized clinical trial was designed to compare the efficacy of ATRA-ATO vs. ATRA-ATO plus chemotherapy in all-risk patients with APL (15), but the results have not yet been published.

Our previous study found that WBC count can be conveniently used to direct cytorreduction chemotherapy during induction treatment for low-intermediate risk APL. When

WBC count is between 4x10<sup>9</sup>/l and 15x10<sup>9</sup>/l, cytotoxic drugs could be initiated to control leukocytosis (8). However, for patients with different types of WBC count multiplication rate, single WBC count may be inadequate to decide on cytorreduction therapy. For slow type of WBC count multiplication, cytorreduction therapy may be optional, even if WBC count increases to >10x10<sup>9</sup>/l. However, patients whose WBC count doubles rapidly, cytorreduction therapy should be considered even if WBC count is <10x10<sup>9</sup>/l because of DS risk. Hence, this study attempted to establish the effects of WBC dynamic changes along with static WBC count on early adverse events including early death, DS, grade 3-4 infection and bleeding.

Since there were no similar studies to be referred, we defined rapid WBC multiplication as WBC count >4x10<sup>9</sup>/l and multiplication time <3 days. It was a grouping method based on clinical experience. Comparison results indicated that patients with rapid WBC multiplication rate had higher possibility of DS and grade 3-4 bleeding, which was consistent with significantly higher peak WBC count in patients with rapid WBC multiplication. However, these adverse effects did not increase the incidence of early death. Multivariate analysis

WBC, white blood cell; CT, chemotherapy.

further proved that WBC count in chemotherapy was the most important factor for DS, and WBC multiplication rate was closely related to serious bleeding events.

The main limitation of this study was its retrospective design. In this study, baseline characteristics between the two groups were not statistically equal, especially WBC count at diagnosis. However, mean WBC count at diagnosis in both groups was less than normal level. Further multivariate analysis showed that the WBC count at diagnosis was not the most important factor for DS, early mortality and grade 3-4 bleeding, compared to other three factors. To some extent, multivariate analysis corrected the bias caused by differences in baseline characteristics. Different from previous research,

this study collected patient's data from another hospital, and all patients were treated with ATRA plus ATO. However, we obtained similar result that WBC count at chemotherapy initiation was associated with DS.

Overall, WBC count at chemotherapy initiation along with WBC multiplication rate could direct the timing of cytorreduction chemotherapy during induction treatment in newly diagnosed acute promyelocytic leukemia with low-intermediate risk.
