Edited by Angel Rubio, Max Planck Institute for the Structure and Dynamics of Matter, Hamburg, Germany, and approved August 20, 2019 (received for review May 15, 2019)

Quantum materials are amenable to nonequilibrium manipulation with light, enabling modification and control of macroscopic properties. Light-based augmentation of superconductivity is particularly intriguing. Copper-oxide superconductors exhibit complex interplay between spin order, charge order, and superconductivity, offering the prospect of enhanced coherence by altering the balance between competing orders. We utilize terahertz time-domain spectroscopy to monitor the c-axis Josephson plasma resonance (JPR) in  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  ( $x = 0.115$ ) as a direct probe of superconductivity dynamics following excitation with near-infrared pulses. Starting from the superconducting state, c-axis polarized excitation with a fluence of  $100 \mu\text{J}/\text{cm}^2$  results in an increase of the far-infrared spectral weight by more than an order of magnitude as evidenced by a blueshift of the JPR, interpreted as resulting from nonthermal collapse of the charge order. The photoinduced signal persists well beyond our measurement window of 300 ps and exhibits signatures of spatial inhomogeneity. The electrodynamic response of this metastable state is consistent with enhanced superconducting fluctuations. Our results reveal that  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  is highly sensitive to nonequilibrium excitation over a wide fluence range, providing an unambiguous example of photoinduced modification of order-parameter competition.

superconductivity | cuprates | charge ordering

High-temperature superconductivity in the cuprates can coexist or compete with a multitude of other phenomena, including charge and spin order, pair density waves, and the pseudogap (1–4), all of which have observable signatures in the linear or transient electrodynamic response (5). A key question for the cuprates is the extent to which the underlying interactions can be manipulated to alter the macroscopic properties. Ultrafast pump–probe spectroscopy provides a unique means to initiate and interrogate nonequilibrium dynamics and property control in superconductors (6, 7).

Evidence of transiently enhanced interlayer tunneling has been reported in several cuprates following selective phonon pumping (8–10) or intense near-infrared excitation (11). In these experiments, the c-axis Josephson plasma resonance (JPR) serves as a reporter of the interlayer tunneling which, in general, scales with the superfluid spectral weight (12). Upon applying intense near-infrared pump excitation starting above the transition temperature  $T_c$ , Nicoletti et al. (11) observed a blueshift of the plasma resonance relative to the below  $T_c$  equilibrium response. The plasma resonance decayed after several picoseconds and was interpreted in terms of transient superconductivity. Similar dynamics were subsequently observed in both  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  and  $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$  over a range of doping levels and excitation conditions. More recently, in  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  ( $x = 0.095$ ), a longer-lived (>50 ps) collective response was observed subsequent to photoexcitation at  $T < T_c$  in which the JPR appeared to split into 2 distinct longitudinal modes (13), reminiscent of the static electrodynamic response in bilayer cuprates (14–16). Further, no pump-induced

effect was observed above  $T_c$ . Notably, the  $x = 0.095$  material does not exhibit robust charge or stripe order (17).

In this report, we clarify the details of the photoinduced order parameter control in the cuprates, by performing temperature and fluence-dependent c-axis measurements on materials with equilibrium signatures of phase competition. We present near-infrared pump, THz probe experiments of  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  ( $x = 0.115$ ), for which we observe distinct dynamics above and below  $T_c$ . The doping  $x = 0.115$  is close to the anomalous  $x = 1/8$  composition where 3D superconductivity is maximally suppressed by robust charge and stripe order (2, 18–20). At  $x = 0.115$ , charge order, spin order, and 3D superconductivity onset at  $T_{co} = 53$  K,  $T_{so} = 40$  K, and  $T_c = 13$  K, respectively (17). In this compound  $T_c$  is high enough to enable initiating dynamics from within the superconducting state. The  $\text{La}_{1.885}\text{Ba}_{0.115}\text{CuO}_4$  crystal was cut and polished to expose the *a*-*c* plane with a large area of  $5 \text{ mm} \times 5 \text{ mm}$ . Temperature-dependent Fourier transform infrared spectroscopy (FTIR) measurements were carefully performed to provide a baseline static characterization of the electrodynamic response (see *SI Appendix, section S1* for details).

The static and dynamic reflectivity of LBCO were measured as a function of temperature and fluence using terahertz time-domain

## Significance

The emergence of superconductivity in high-temperature cuprates arises out of a rich landscape of competing order. For example, stripe order can hoard the electrons needed to form Cooper pairs and establish superconductivity. Intriguingly, the complex interactions of such intertwined orders can be manipulated with light, where nonequilibrium dynamics alter the primacy of one order over another. Following photoexcitation of  $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$  ( $x = 0.115$ ) with near-infrared pulses, we observe a long-lived state that exhibits enhanced superconducting correlations well above the equilibrium superconducting transition temperature. Our analysis reveals that this metastable phase arises from a collapse of stripe order, providing an important demonstration of light-directed control in quantum materials.

**Fig. 1.** (A) Schematic of the 1.55-eV pump THz probe experiment on LBCO crystal with pump and probe polarization along c axis. The illustration depicts the superconducting state with electron pairs tunneling along the c axis. (B) Equilibrium THz reflectivity above and below  $T_C$  at 30 and 7 K, respectively. The dotted line is beyond our experimentally accessible spectral range and is a guide to the eye. (C) Time-dependent relative change in the THz electric field amplitude after excitation at various pump fluences (at 7 K). (D) Temperature versus hole doping phase diagram of  $L_{2-x}Ba_xCuO_4$ . Adapted with permission from ref. 17. Regions of the phase diagram include bulk superconductivity (SC) at onset temperature  $T_C$ , spin ordering (SO) at temperature  $T_{SO}$ , charge ordering at  $T_{CO}$ , and low-temperature structural transition  $T_{LT}$ . The initial temperature at 7 K for  $x = 0.115$  is plotted in red, and the color dots mark the estimated lattice temperature after pump excitation and e-ph thermalization has occurred (colors corresponding to pump fluences shown in C).

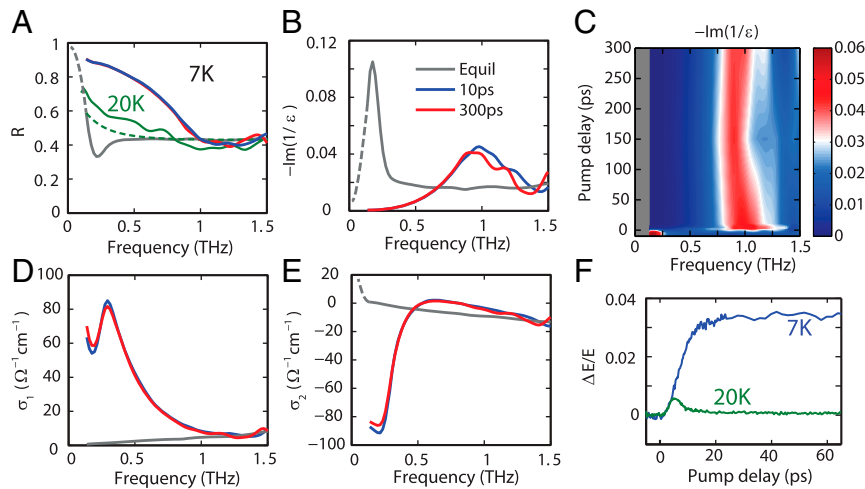

spectroscopy (0.15 to 2 THz). As shown in Fig. 1A, both the near-infrared pump (1.55 eV) and the THz probe pulses are polarized along the c axis. The static THz reflectivity is plotted in Fig. 1B, showing a flat response at 30 K (gray line, with a slight upturn below 0.5 THz). In the superconducting state (7 K, blue curve) a sharp reflectivity edge emerges around 200 GHz, a hallmark of the interlayer JPR effect in agreement with previous studies for this doping (11).

For the dynamics measurements, we first performed 1-dimensional scans, where the photoinduced change in the peak electric field of the single-cycle THz pulse ( $\Delta E/E$ ) is measured as a function of pump-probe delay. These raw unprocessed data unambiguously highlight important features of the electrodynamic response. Fig. 1C plots 1-dimensional scans ( $\Delta E/E$  peak scans) for various fluences, starting from an initial temperature of 7 K, well into the superconducting state. The dynamics exhibit a long-lived response with an initial risetime of several picoseconds. The magnitude of the  $\Delta E/E$  signal slightly increases from 50 to 100  $\mu\text{J}/\text{cm}^2$ , followed by a strong decrease in amplitude at higher fluences up to 760  $\mu\text{J}/\text{cm}^2$ . The observed fluence dependence indicates dynamics that are distinct from a photoinduced decrease in the condensate density with a commensurate increase in the quasiparticle density. In that scenario,  $\Delta E/E$  would increase in magnitude with increasing fluence.

Calculations using the 2-temperature model of the initial electron-phonon (e-ph) thermalization (see *SI Appendix, section S3* for details) indicate a rise in the final temperature that increases with fluence (after several picoseconds when the plateau in the data in Fig. 1C is reached). Fig. 1D displays the phase diagram of LBCO (reproduced from ref. 17) with color-coded dots (corresponding to

the fluences used in Fig. 1C) indicating the final temperature after thermalization. Clearly, the amplitude of  $\Delta E/E$  decreases with increasing fluence as  $T_{CO}$  is approached after the initial e-ph thermalization. This indicates that the strongest photoinduced response occurs for fluences that do not heat the sample above  $T_{CO}$ . We refer to 50 to 380  $\mu\text{J}/\text{cm}^2$  as the low-fluence regime where the quasiequilibrium temperature stays below  $T_{CO}$ . The data in Figs. 2 and 3 reveal that the dynamics are dramatically different for low- and high-fluence ( $>380 \mu\text{J}/\text{cm}^2$ ) regimes spanning  $T_{CO}$ . The difference in dynamics is evident in Fig. 1C, where the 760- $\mu\text{J}/\text{cm}^2$  data exhibit an exponential decay in contrast to the plateau apparent in the low-fluence data.

We now discuss the full spectroscopic response of the dynamics, considering first low-fluence optical excitation of LBCO (100  $\mu\text{J}/\text{cm}^2$ ) obtained starting from an initial temperature of 7 K. The optical properties of the photoexcited region were extracted using a layered model to account for the penetration depth mismatch between the pump and probe beams (see *SI Appendix, section S2*). Fig. 2A shows the photoinduced reflectivity (blue curve at 10 ps, red curve at 300 ps), revealing a large reflectivity increase extending out to 1 THz, corresponding to an increase in the plasma frequency from  $\sim 0.2$  to 0.9 THz. This is more clearly revealed in Fig. 2B and C showing the loss function  $-\text{Im}(1/\epsilon)$  (where  $\epsilon = \epsilon_1 + i\epsilon_2$  is the c-axis dielectric response) which peaks at the plasma frequency. Importantly, there is no sign of decay of the photoinduced state over the measured temporal window, indicating a metastable state that persists beyond 300 ps. Fig. 2D and E show the associated c-axis optical conductivity ( $\sigma = \sigma_1 + i\sigma_2$ ) highlighting an important observation. Namely, there is a peak in  $\sigma_1$  at 0.3 THz signifying

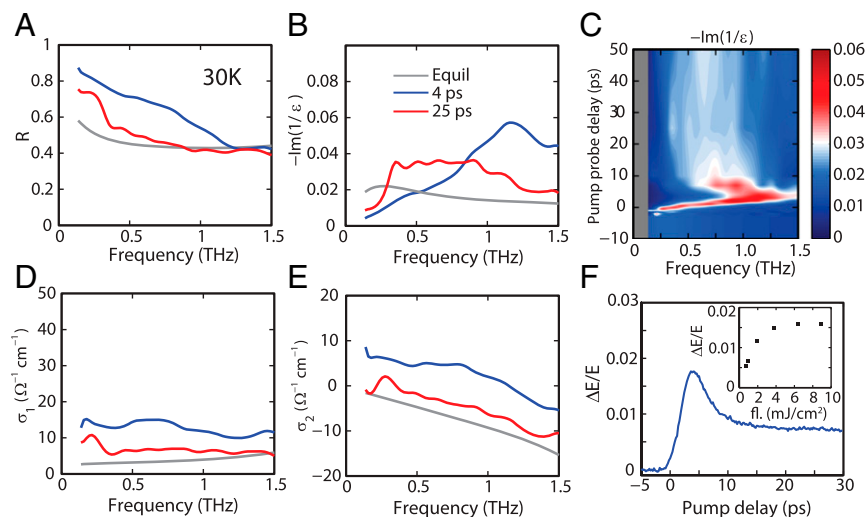

**Fig. 2.** Extracted c-axis THz optical properties of LBCO at different pump-probe delays after photoexcitation (colored) with  $100 \mu\text{J}/\text{cm}^2$  and at equilibrium (gray). All data have been taken at 7 K below  $T_C$  except for the green curves in A and F which were taken at 20 K. (A) Reflectivity at 7 K before (gray) and after photoexcitation (colored) at different pump-probe delays. Plotted in green is the equilibrium (dotted) reflectivity and largest photoinduced change (solid) in reflectivity at 20 K. (B) Loss function  $-\text{Im}(1/\epsilon)$ . Dashed gray line is beyond our spectral resolution and is a guide to the eye. (C) Spectral evolution of the loss function after photoexcitation. (D and E) Real and imaginary parts of the THz conductivity. (F) Peak of  $\Delta E/E$  THz transient after photoexcitation at 7 and 20 K.

dissipation in the c-axis THz transport. In contrast, in equilibrium for a superconductor,  $\sigma_1$  at frequencies greater than zero but less than twice the superconducting gap approaches zero (solid gray line in Fig. 2D). This origin of the peak in  $\sigma_1$  arising after photoexcitation will be discussed below. Finally, the solid green line in Fig. 2A shows the spectral response at 10 ps delay for a fluence of  $100 \mu\text{J}/\text{cm}^2$  taken at an initial temperature of 20 K—that is, above  $T_C$ . There is an increase in the reflectivity, arguably with the development of a weak plasma edge. However, as shown in Fig. 2F, the response is much smaller and shorter lived in comparison to dynamics initiated from within the superconducting state. In short, the emergence of a robust metastable state upon low-fluence photoexcitation requires starting from the superconducting state while remaining below  $T_{co}$  after e-ph thermalization.

To complete the data discussion, we now consider the high-fluence dynamics. Fig. 3 shows the spectroscopic results for high-

fluence excitation at  $9 \text{ mJ}/\text{cm}^2$  which leads to a final temperature greater than  $T_{co}$ . Fig. 3A reveals an increased reflectivity starting from an initial temperature of 30 K. At early times a broad peak emerges in the loss function (shown in Fig. 3B and C) that rapidly broadens and decays on an  $\sim 10$ -ps timescale. There is a corresponding increase in  $\sigma_1$  and  $\sigma_2$  (Fig. 3D and E), although there are no well-defined peaks as for the low-fluence results. Fig. 3F reveals the rapid decay in the transient  $\Delta E/E$  with  $9\text{-mJ}/\text{cm}^2$  excitation, with the inset showing a saturation of the dynamics with increasing fluence. The plateau in the  $\Delta E/E$  scans following the initial exponential decay is presumably associated with heating, leading to a broad and featureless optical conductivity from 0.1 to 1.5 THz. The broadened plasma edge that appears after the arrival of the pump pulse is qualitatively in agreement with the previous study by Nicoletti et al. (11). Given the relatively small value of  $\sigma_1$ , this could indicate the presence

**Fig. 3.** Extracted c-axis THz optical properties of LBCO at different pump-probe delays after photoexcitation (colored) with  $9 \text{ mJ}/\text{cm}^2$  and at equilibrium (gray). All data taken at 30 K above  $T_C$  and below  $T_{co}$ . (A) Reflectivity and (B) loss function,  $-\text{Im}(1/\epsilon)$  at different pump-probe delays. (C) Spectral evolution of the loss function after photoexcitation. (D and E) Real and imaginary parts of the THz conductivity at different pump-probe delays. of enhanced superconducting correlations associated with the unambiguous transient blueshift of the plasma frequency. Summarizing, the high-fluence transient response evolves at temperatures above  $T_{co}$  and is short-lived in contrast to the low-fluence metastable results presented in Fig. 2, implying that the 2 features correspond to distinct states.

We now discuss the origin and nature of the low-fluence photoinduced metastable electrodynamic response (Fig. 2). For  $100 \mu\text{J}/\text{cm}^2$ , the temperature following e-ph thermalization is  $\sim 35$  K. In equilibrium, 35 K is within the charge-ordered, non-superconducting region that is spectrally featureless at THz frequencies. In contrast, the low-fluence metastable state produced by c-axis excitation exhibits unique spectroscopic features in the loss function  $-\text{Im}(1/\epsilon)$  (Fig. 2 B and C) and conductivity (Fig. 2 D and E) that are indicative of a nonequilibrium metastable state. Importantly, the plasma frequency ( $\omega_p$ ) is blueshifted by a factor of 4.5 upon photoexcitation (from  $0.2 \rightarrow 0.9$  THz) corresponding to an increase of the low-energy spectral weight ( $\Sigma$ ) by a factor of 20 (i.e.,  $\Sigma \propto \rho_p^2$ ). This is a robust observation, independent of the microscopic origin of the electrodynamic response. Additionally, the spectral weight must originate from energies beyond the 1.5-THz regime probed here because the equilibrium condensate spectral weight (Fig. 4A) is far too small to account for the factor of 20 increase. A change in the c-axis response may also arise from structural distortions affecting interlayer coupling independent of a change in the in-plane superfluid density (21). Although our measurements are not directly sensitive to structural distortions, we estimate the metastable phase to be at  $\sim 35$  K which is still below the low-temperature orthorhombic to tetragonal transition occurring at 53 K (22). As such, this is not likely to be the cause of the increase in  $\Sigma$ . We next show that a more likely scenario for the increase in  $\Sigma$  is photoinduced collapse of charge/stripe order whereby spectral weight originally at energies above the charge density wave (CDW) gap scale is made available for enhanced c-axis transport.

A well-known approximate scaling relationship (valid for both c-axis and ab plane) for the cuprates is  $\rho_o = 120\sigma_{dc}T_c$ , where  $\rho_o$  is the superfluid density  $\propto(2)$  and  $\sigma_{dc}$  is the zero-frequency conductivity measured just above  $T_c$  (23). Fig. 4A shows the product  $\sigma_{dc}T_c$  versus  $\rho_o$  for  $x = 0.115$  doping measured in this study, and for  $x = 0.95$  and  $x = 0.145$  taken from ref. 22 For  $x = 0.115$  at 7 K,

the JPR appears near the renormalized superconducting plasma frequency  $\omega'_p = 6.7 \text{ cm}^{-1}$  (200 GHz). The unscreened plasma frequency is given by  $\omega_p = \omega'_p \sqrt{\epsilon_L \epsilon_L} \sim 30$  giving a superfluid density  $\rho_o \equiv \omega_p^2 = 1.3 \times 10^3 \text{ cm}^{-2}$  (This is taken to be very near the superfluid density at  $T = 0$  K.) The conductivity just above  $T_c = 13$  K is taken as  $\sigma_{dc} \sim 0.8 \Omega^{-1}\text{cm}^{-1}$ , estimated from transport measurements on a similar doping of  $x = 0.11$  (24). As seen in Fig. 4A, the  $x = 0.115$  doping is consistent with  $\rho_o = 120 \sigma_{dc}T_c$  plotted as a dashed line. We now extend this concept to the photoinduced metastable state which, as described above, exhibits a large increase in spectral weight.

From the photoinduced blueshift of the plasma edge ( $\omega'_c \sim 0.9$  THz or  $30 \text{ cm}^{-1}$ ) it is possible to determine the photoinduced density  $\rho_c$ . This estimate from experimental data gives  $\rho_c = 2.7 \times 10^4 \text{ cm}^{-2}$ , yielding  $\rho_c/\rho_o \sim 20$  as mentioned above. We now assume the validity of the scaling relation  $\rho_c = 120 \sigma_{co}T_{co}$  where  $\sigma_{co} \sim 3 \Omega^{-1}\text{cm}^{-1}$  is the conductivity just above the charge-ordering temperature ( $T_{co} = 53$  K). From this we obtain  $\rho_c/\rho_o \sim \sigma_{co}T_{co}/\sigma_cT_c \sim 15$ , in reasonable agreement with experiment. The product  $\sigma_{co}T_{co}$  is plotted in Fig. 4A as a red data point and lies on the dashed line given by  $\rho_s = 120 \sigma_{dc}T_c$ . This suggests that c-axis spectral weight initially tied up in charge order is released upon photoexcitation leading to the blueshift of the plasma edge. We note that the precise microscopic reason for the photoinduced collapse of charge order upon c-axis interband excitation is not understood and is a topic for future investigation, beyond the scope of the present study.

The peak in the loss function cannot be simply described as an enhanced plasma edge with increased interlayer tunneling arising from the collapse of the charge order. This is because we have a peak in  $\sigma_1$  at a nonzero frequency (Fig. 2D). In principle, 2 inequivalent junctions (with different interlayer spacing) do yield 2 distinct longitudinal JPRs at different frequencies. For example, Sm-doped  $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$  (LSCO), is composed of a stack of inequivalent Josephson junctions. Out-of-phase oscillations of the 2 longitudinal modes result in a transverse mode with a resonance frequency intermediate to the 2 JPRs with a corresponding peak in  $\sigma_1$  (16, 25). In such a case, the spectral weight would be associated with a pure superfluid response, which is certainly intriguing since our LBCO sample is (as discussed above) at  $\sim 35$  K following e-ph equilibration (i.e.,  $\sim 2.7 T_c$ ). It is, however, not clear how photoexcitation could lead to uniform creation of a well-defined

**Fig. 4.** (A) Plot of the superfluid density  $\rho_s$  versus the product of the zero-frequency conductivity ( $\sigma_{dc}$ ) and the superconducting transition temperature  $T_c$  for several dopings of LBCO ( $\sigma_{dc}$  is the conductivity measured just above the superconducting transition). The values for  $x = 0.95$  and  $x = 0.145$  were taken from ref. 22. The dashed line is the universal scaling relation for cuprates  $\rho_s = 120\sigma_{dc}T_c$  found by Homes et al. (23) (B) Schematic of anisotropic effective medium theory along the c axis with regions of different dielectric constants  $\epsilon_1$  and  $\epsilon_2$  and filling fractions  $f_1$  and  $f_2$ , respectively. The superconducting volume is depicted with dark ellipses and the transformed region is in blue. (C) Real (red) and imaginary (blue) parts of the THz conductivity after photoexcitation with  $100 \mu\text{J}/\text{cm}^2$  at 7 K. Experimental data are plotted with dots and the effective medium model with solid lines.

microscopic bilayer structure, although spectroscopic aspects of this are present in the non-charge-ordered LBCO ( $x = 0.095$ ) (13). However, for  $x = 0.115$ , charge-order collapse plays a dominant role as described above. As such, we consider an alternative scenario based on photoinduced mesoscopic inhomogeneity.

The simplest effective medium theory for an anisotropic layered crystal (appropriate to c-axis cuprates) is schematically depicted in Fig. 4B where regions are transformed into a metastable state (blue) while others remain untransformed (dark ellipses). The domain boundaries of the 2 different phases are along the a-b plane giving rise to regions with differing c-axis coupling strengths. The dark horizontal stripes represent the insulating barriers between  $\text{CuO}_2$  planes which give rise to the Josephson effect along the c axis. The effective dielectric response  $\epsilon_{\text{eff}}$  is given as  $1/\epsilon_{\text{eff}} = f_1/\epsilon_1 + f_2/\epsilon_2$  where  $f_1$  and  $f_2$  are the volume fractions corresponding to regions with complex dielectric function  $\epsilon_1$  and  $\epsilon_2$ , respectively (26). Taking  $f_1$  as the superconducting volume fraction (having the 7 K equilibrium response), and  $f_2$  as a Drude response (with a finite scattering rate of 0.36 THz) yields the fit to the experimental data shown in Fig. 4C. For additional details regarding the model and fit we refer the reader to *SI Appendix, section S4*. Notably, the peak in  $\sigma_1$  corresponding to a photoinduced transverse mode is accurately reproduced with this model taking  $f_1 = 0.02 \pm 0.01$  and  $f_2 = 0.98 \pm 0.01$ . While the general features of  $\sigma_2$  are reproduced by the effective medium model, an exact fit was not possible. We note that errors in extracting  $\sigma_2$  from experiment are generally more difficult in comparison to  $\sigma_1$  as this depends sensitively on changes in phase of the terahertz pulse.

Taking the fits as representative of the photoinduced state leads to some interesting conclusions. First, the preponderant component consisting of a Drude response is consistent with the picture presented above that the pump destroys the charge/spin order. Second, a small but nonnegligible superconducting volume fraction ( $\sim 2\%$ ) is required to obtain the spectral response in Fig. 4C. This indicates that even though the temperature is more than 2 times greater than the equilibrium  $T_c$ , regions of superconductivity persist. Furthermore, the Drude response (associated with  $f_2$ ) is anomalous as it exhibits a small scattering rate of

0.36 THz. This is surprising for a nonsuperconducting c-axis response and has not been observed in the equilibrium c-axis response for any cuprate material. We suggest that the origin of this enhanced response arises from incipient superconducting correlations that enhance the c-axis conductivity as has been theoretically discussed (27, 28). This is consistent with the experimental observation that the observed metastability requires starting from an initial superconducting state and that a nonzero superconducting volume fraction persists after photoexcitation. Previous pump-probe studies on the cuprates have also observed long-lived dynamics after photoexcitation of the superconducting state, although the fluence dependence differs from what we have observed (29–31). In these studies the slow relaxation rate of the quasiparticles is described by a persistent phase separation along the  $\text{CuO}$  planes which may be a general feature in the cuprates and responsible for the long-lived state we observe. It will be important to pursue comparative experimental studies as a function of doping and excitation fluence and to gain additional insight into the nature of the metastability we have observed in LBCO. Such studies will also benefit from theoretical investigations of the origin of metastability in materials with competing order (32).

In summary, low-fluence photoexcitation favors the establishment of a long-lived state with superconductivity playing an important role. Additional experiments are required to fully characterize the observed metastable response and the effective medium description of mesoscale inhomogeneity that includes a superfluid response. Our results raise crucial theoretical questions including the origin of the superconductivity and the physics and surprisingly long lifetime of the metallic state. The observed long lifetime bodes well for performing additional experiments, including time-resolved nanoscopy to spatially resolve the photoinduced state.
