INTRODUCTION

Currently, approximately one in eleven US adults have diabetes, and more than one in three are pre-diabetic.¹ Additionally, it is estimated that approximately two in five US adults will develop diabetes, with most of these cases being type 2 diabetes (T2D).² According to data (2011–2012) recently published by Menke *et al*,³ 14.3% of US adults (over 20 years of age) were diabetic (9.1% were diagnosed as being diabetic, 5.2% having undiagnosed diabetes) and 38% were pre-diabetic, totalling 52.3% of US adults having pre-diabetes or diabetes. The burden of undiagnosed diabetes seems to have increased in parallel to the above estimates. Among people with diabetes, more than one-third went undiagnosed overall (36.4% (95% CI 30.5% to 42.7%)). Additionally, this burden was even higher among non-Hispanic Asian participants (50.9%; P=0.004) and Hispanic participants (49.0%; P=0.02).³ In view of this, it can be concluded that using fasting glucose, oral glucose tolerance test (OGTT) or A1c may not be the most effective early screening tool for T2D. Thus, incorporating fasting insulin and especially insulin assay after an OGTT as enhanced screening methods may help to increase the ability to detect diabetes and pre-diabetes, allowing earlier intervention to prevent diabetic complications.

FASTING AND POSTPRANDIAL INSULIN FOR EARLY DIAGNOSIS OF T2D

Kraft patterns

Hyperinsulinaemia is thought to be aetiological in hypertension, obesity, atherosclerosis, microvascular disease, neurodegenerative disorders, idiopathic peripheral neuropathy and certain cancers,^{4,5} and is associated with idiopathic tinnitus, vertigo and hearing loss.⁶ A key research paper published in 1975 by Dr

Joseph R Kraft comprised 3650 patients who were randomly referred for glucose tolerance testing.⁷ Dr Kraft described five different insulin patterns in response to a 100 g glucose load administered over 3–5 hours with insulin levels assessed at baseline, 30, 60, 120, and at minimum, 180 min. Further 240 and 300 min insulin levels were also considered in certain instances. Pattern I was labelled as the normal insulin tolerance, where the fasting insulin levels were between 0 and 30 microunits, with peak insulin production demonstrated on 30 or 60 min levels, followed by return to fasting range at 120 or 180 min, and stabilised on fasting levels beyond 180 min. Pattern II accounted for those with normal insulin peak but delayed return to baseline fasting levels, and pattern III consisted of subjects with delayed insulin peak appearing later than 60 min. Pattern IV was labelled in cases who had baseline fasting levels more than 50 microunits. The last pattern, pattern V, had patients with insulin levels of less than 30 microunits at all times.⁷

These insulin/glucose tolerance tests were then compared with standard glucose tolerance tests. A score of 0 Wilkerson point was labelled as normal, ½, 1 and 1 ½ as equivocal, and 2 or 3 as diagnostic for diabetes. In this research by Kraft, 47% had normal glucose tolerance, 34% had equivocal results and 19% were positive for diabetes. The assessment of insulin levels was then performed. Pattern I was classified as normal, patterns II, III and IV as borderline or diagnostic for diabetes, and pattern V as low insulin. This revealed that in the normal glucose tolerance group 2.5% had low insulin, 14% were borderline diabetic and 50% had diabetic insulin levels, with only 33% having a normal insulin response to an OGTT. In the equivocal glucose tolerance group, 10% had normal

insulin levels, while 90% had diabetic patterns, and in those with glucose tolerance test positive for diabetes, 100% of the subjects had diabetic insulin patterns. This includes 62 cases who had pattern V (low insulin) and a clear hyperglycaemic response consistent with type 1 diabetes. Kraft's research indicated that 75% of those subjects with normal or equivocal glucose tolerance tests (n=2940) had borderline or abnormal insulin response patterns (patterns II, III and IV) and likely had 'diabetes in-situ' or 'occult diabetes'.⁷

Another similar study by Dr Kraft produced identical conclusions and also compared two different methods of insulin estimation (RIA: radioimmunoassay and MEIA: microparticle enzyme immunoassay). Using the RIA 87.8% (n=303) and with MEIA 79.1% (n=273) of subjects with a normal or equivocal glucose tolerance test (Wilkinson score 0, ½, 1 or 1 ½) (n=345) were found to have abnormal insulin response patterns (pattern II, III, IV). Those with overt diabetes on glucose tolerance test (Wilkinson score 2 or 3) inevitably had abnormal or reduced insulin response patterns.⁸

The flaw in Kraft's original research is that it did not account for a number of different insulin patterns, including those who had a fasting level between 30 and 50 microunits. Working with Dr Kraft, Crofts and colleagues⁹ redefined Kraft's original patterns to ensure all tests could be categorised. Patterns I, IV and V remained the same, but patterns II and III were expanded to include those with a fasting insulin between 31 and 49 microunits (inclusive). Crofts *et al* then reanalysed the data set using WHO glucose disorder definitions. Of the 3428 people with either impaired glucose tolerance or diabetes, the vast majority (93%) also had a hyperinsulinaemic pattern. Hyperinsulinaemia also affected approximately 75% of the people with normal glucose tolerance (n=4030).

Hayashi patterns

More recent prospective research by Hayashi *et al*¹⁰ further confirmed the above findings and showed that insulin concentrations during glucose tolerance test strongly predict the development of T2D. They followed 400 non-diabetic Japanese Americans for 10–11 years to assess incidence of T2D. Each participant underwent insulin estimation at baseline, 30, 60 and 120 min intervals during a 2-hour 75g OGTT. The insulin response patterns were classified into five types, distinct from Kraft's. Pattern 1 included initial insulin peak within 30 min, and higher insulin level at 60 min than at 120 min; pattern 2, with similar initial peak, but 1-hour level was less than or equal to level at 2 hours; pattern 3, initial

peak within 1 hour; pattern 4, with initial peak within first 2 hours, and a lower level at 30 min than at 60 min; and pattern 5, with initial peak within 2 hours, and equal or higher level at 30 min as compared with 60 min. After the follow-up 86 cases developed T2D. Patterns 1, 2, 3, 4 and 5 demonstrated a cumulative incidence of 3.2%, 9.8%, 15.4%, 47.8% and 37.5%, respectively. The multiple-adjusted ORs for developing T2D were 12.55 (95% CI 4.79 to 32.89) for pattern 4, and 8.34 (95% CI 2.38 to 29.27) for pattern 5, as opposed to patterns 1 and 2. Also, this risk was independent of insulin secretion and sensitivity.

FASTING INSULIN RESPONSE ASSESSMENTS

Multiple-sampled glucose tolerance tests required to produce the Kraft and Hayashi patterns are resource-intensive. This may explain the popularity of fasting measures such as homeostasis modal assessment (HOMA). HOMA was originally developed to assess insulin resistance (HOMA-IR), pancreatic beta-cell function (HOMA-β) and insulin sensitivity (HOMA-S) from fasting plasma insulin and glucose concentrations.¹¹ This is based on the relationship between basal insulin and glucose concentrations reflecting hepatic glucose output and insulin secretion. Normal pancreatic beta-cell function or insulin sensitivity is considered 100% and normal insulin resistance is 1.0. HOMA variants can be determined either by using the calculations shown in figure 1 or by using HOMA 2 from the online calculator (<https://www.dtu.ox.ac.uk/homacalculator/>). HOMA2 uses model-derived estimates, which better accounts for variations in glucose resistance and when plasma glucose concentrations are above 10 mmol/L.¹² However, there are numerous flaws to using measures based on fasting insulin as discussed below.

Flaws in using fasting insulin resistance models

There are several flaws with using insulin resistance models that are based on fasting insulin and glucose concentrations, including the physiology of insulin secretion and basal levels, the use of insulin resistance as the disease state of concern, and implementation and interpretation of the test itself.

Insulin physiology

Plasma insulin concentrations are labile due to the physiology of insulin release from the pancreas. Insulin is released in a pulsatile manner leading to oscillatory concentrations in the blood. These oscillations have a slow ultradian periodicity (~140 min), which is modulated by

$$HOMA-IR = \frac{Glucose \times Insulin}{22.5}, \quad HOMA-\beta = \frac{20 \times Insulin}{Glucose - 3.5} \%, \quad HOMA-S = \frac{1}{HOMA-\beta}$$

Figure 1 HOMA calculations where glucose is mmol/L and insulin is mU/L.¹⁵ HOMA, homeostasis model assessment; HOMA-β; HOMA to assess pancreatic beta-cell function; HOMA-IR, HOMA to assess insulin resistance; HOMA-S, HOMA to assess insulin sensitivity.

a small-amplitude high-frequency oscillation (periodicity 3–10 min).^{13,14} It is hypothesised that the periodic release of insulin prevents downregulation of receptors leading to insulin resistance. Loss of these regular insulin oscillations is considered to be an early indicator of diabetes.

However, these oscillations make a single sample of insulin impractical for clinical practice, as it will be unknown where the insulin levels lie in these periodic cycles. It has been suggested that if fasting insulin concentrations are required, then the average of three samples, taken at 5 min intervals, should be used; however, this rarely is done in clinical practice.¹⁵

Reproducibility of single fasting insulin measures

Insulin resistance is extensively assessed in epidemiological studies, usually by measures that use fasting insulin. However, there are a number of questions about the reproducibility of fasting insulin. Coefficient of variation (CV) for fasting insulin has been reported between 25% and 50%,¹⁶ whereas other studies have reported CV of HOMA closer to 10%.¹⁵ Further work is needed on the reproducibility of measures using fasting insulin if these are to be used more in the clinical setting.

INSULIN RESISTANCE

There is a current argument as to whether we should be more concerned about insulin resistance or hyperinsulinaemia. As discussed by Crofts,⁴ insulin resistance is the state where the body does not respond to normal levels of insulin. The gold standard test for insulin resistance is the hyperinsulinaemia-euglycaemia clamp test, which assesses the glucose uptake rate. Tests such as HOMA have been validated against the clamp test. However, it is currently being argued that insulin resistance per se is not the major cause of physiological damage. People who are insulin-resistant become hyperinsulinaemic following a carbohydrate load, and as discussed above hyperinsulinaemia is also linked to adverse pathophysiological states. Since hyperinsulinaemia generally results from a postprandial state,⁹ it remains unknown whether fasting measures such as HOMA are sufficiently accurate to predict postprandial hyperinsulinaemia.

RECOMMENDED ASSAY

Although it is hyperinsulinaemia that is best assessed following an oral glucose load, there is debate as to the best test protocol. Currently, the two published tests are the Kraft and Hayashi protocols described above. The overarching principles for the two tests are the same.

The patient prepares by having at least 2 weeks of a diet containing at least 150 g carbohydrate per day.⁷ After an overnight fast (>10 hours), the patient has a 75 g OGTT with plasma glucose and insulin sampled at baseline, 30, 60, 120 and 180 min. (NB: if only the Hayashi protocol is being followed, then the 180 min sample may be omitted.) The results can be interpreted as per tables 1 and 2. It should be noted that the original Kraft

Table 1 Kraft pattern results⁹ (used with permission)

Kraft pattern	Description
Pattern I Normal insulin	<ul style="list-style-type: none"> ▶ Fasting insulin ≤30 µU/mL ▶ 30 min or 1-hour peak ▶ 2-hour+3-hour sum <60 µU/mL
Pattern IIA Borderline	<ul style="list-style-type: none"> ▶ Fasting insulin ≤50 µU/mL ▶ 30 min or 1-hour peak ▶ 2-hour+3-hour sum ≥60, <100 µU/mL <p>OR</p> <ul style="list-style-type: none"> ▶ Fasting insulin 31–50 µU/mL ▶ 30 min or 1-hour peak ▶ 2-hour+3-hour sum <60 µU/mL
Pattern IIB Hyperinsulinaemia	<ul style="list-style-type: none"> ▶ Fasting insulin ≤50 µU/mL ▶ 30 min or 1-hour peak ▶ 2-hour+3-hour sum ≥100 µU/mL
Pattern III Hyperinsulinaemia	<ul style="list-style-type: none"> ▶ Fasting insulin ≤50 µU/mL ▶ Delayed peak (2 hours or 3 hours)
Pattern IV Hyperinsulinaemia	<ul style="list-style-type: none"> ▶ Fasting insulin >50 µU/mL
Pattern V Hypoinsulinaemia	<ul style="list-style-type: none"> ▶ All values ≤30 µU/mL

protocol was conducted with a 100 g oral glucose load. If a 75 g load is used, borderline results may also indicate hyperinsulinaemia. Further research is needed to confirm glucose dose and whether the protocol can be simplified.

Thus, a dynamic insulin assay combined with the glucose tolerance test that assesses insulin status following a glucose load is very likely to be worthwhile in adequately assessing the actual presence of diabetes, especially occult or diabetes in situ. Some limitations of the insulin assay include concomitant medications, varying assays, dietary factors (how long a person fasts), cultural and ethnic differences, and age of testing (puberty or postmenopausal for example). Thus, clearly more research is needed, but until then the insulin assay may be an improvement compared with an OGTT alone at diagnosing diabetes.

Table 2 Hayashi pattern results¹⁰

Hayashi pattern	Description
Pattern 1	<ul style="list-style-type: none"> ▶ Peak at 30 min ▶ 60 min >120 min
Pattern 2	<ul style="list-style-type: none"> ▶ Peak at 30 min ▶ 60 min ≤120 min
Pattern 3	<ul style="list-style-type: none"> ▶ Peak at 60 min
Pattern 4	<ul style="list-style-type: none"> ▶ Peak at 120 min ▶ 30 min <60 min
Pattern 5	<ul style="list-style-type: none"> ▶ Peak at 120 min ▶ 30 min ≥60 min

NB: If two equal peaks occur, then the earlier occurrence is deemed to be the peak.

CONCLUSION

Diabetes is now a global pandemic, yet undiagnosed diabetes is a burgeoning and pernicious problem. The need to develop early biomarkers to diagnose diabetes is of utmost importance. The insulin assay, measuring both fasting and after an OGTT, seems to be the earliest biomarker for diagnosing T2D. There is a need to further test insulin assay algorithms and implement these diagnostic tools into the guidelines.
