Abstract

Introduction and Objective: Even though the introduction of less cumbersome anticoagulant agents has improved, the rates of overall anticoagulant treatment in eligible patients with atrial fibrillation (AF) remain to be defined. We aimed to assess the rates of and determinants for the use of anticoagulation treatment before stroke in patients with known AF since the introduction of direct oral anticoagulants (DOAC) in clinical practice. **Methods:** Consecutive patients admitted to an individual stroke unit, from September 2013 through July 2019, for acute ischemic stroke or transient ischemic attack (TIA) with known AF before the event were included in the study. Logistic regression analysis was used to identify independent predictors of the use of anticoagulant treatment. **Results:** Overall, 155 patients with ischemic stroke/TIA and known AF were included in this study. Among 152 patients with a CHA₂DS₂-VASc score > 1, 43 patients were not receiving any treatment, 47 patients were receiving antiplatelet agents, and the remaining 62 patients were on oral anticoagulants. Among 34 patients on DOAC, 13 were receiving a nonlabeled reduced dose and 18 out of 34 patients on vitamin K antagonists had an INR value < 2 at the time of admission. Before stroke, only 34 out of 155 patients (21.9%) were adequately treated according to current guidelines. Previous stroke/TIA was the only independent predictor of the use of anticoagulant therapy. **Conclusions:** Only 21.9% of the patients hospitalized for a stroke or TIA with known AF before the event were adequately treated according to recent treatment guidelines. It is important to improve medical information about the risk of AF and the efficacy of anticoagulants in stroke prevention.

Introduction

Stroke is a leading cause of mortality and long-term disability worldwide. Every year, more than 795,000 people in the USA have a stroke and nearly 1 stroke out of 4 occur in people who have had a previous stroke [1]. Atrial fibrillation (AF) is an independent risk factor for stroke, leading to a 5-fold increase in the annual risk of stroke [2]. Vitamin K antagonists (VKA) reduce the risk of stroke by 62% and that of mortality by 26% with an acceptable risk of bleeding [3, 4]. Indeed, international guidelines currently recommend oral anticoagulation in all patients with risk factors for stroke [5, 6]. Direct oral anticoagulants (DOAC) have radically changed anticoagulation management in AF. Indeed, they can be administered in fixed doses without laboratory monitoring and dose adjustment. Even though the introduction of less cumbersome anticoagulant agents has improved, the rates of overall anticoagulant treatment in eligible patients with AF remain to be defined.

Hence, the aim of the study is to evaluate the rates of and determinants for the use of anticoagulation treatment before stroke in patients with known AF and the adherence to the current treatment guidelines after DOAC availability in clinical practice.

Materials and Methods

Consecutive patients admitted to the Stroke Unit of the University of Perugia, Italy, from September 2013 through July 2019 for acute ischemic stroke or transient ischemic attack (TIA) with known AF before the event were included in this study. Exclusion criteria were intracranial or subarachnoid hemorrhages and cerebral venous thrombosis.

For all of the included patients the following data were prospectively collected: age, gender, comorbidities (hypertension, diabetes mellitus, hyperlipidemia, and previous ischemic stroke/TIA), NIHSS at admission, current smoker status, obesity and alcoholism. Risk of stroke was defined according to the CHA₂DS₂-VASc score [7]. The definition of each piece of collected data has been previously reported [8]. Patients were considered to be adequately treated if they were receiving the following treatment: (1) no treatment in patients with a CHA₂DS₂-VASc score of 0 or women with a CHA₂DS₂-VASc score of 1, (2) oral anticoagulant treatment with VKA with INR between 2 and 3 at time of admission or with DOAC at the labeled dose according to the DOAC summary of product characteristics in patients with a CHA₂DS₂-VASc score >1 or men with a CHA₂DS₂-VASc score of 1. The outcome of this study was the rate of patients adequately treated according to the current treatment guidelines [5, 6].

Categorical data were reported as frequencies and continuous data as means ± SD. Continuous data were compared using Student's *t* test whereas categorical data were compared using the χ^2 test. The reported *p* values were based on two-sided tests. Univariate analysis was used to compare clinical data of AF patients treated or not treated with oral anticoagulant therapy before stroke or TIA. Multivariable regression analysis was used to identify independent predictors of anticoagulant treatment before stroke as a dependent variable. The independent variables included in the analysis were: age, sex, history of stroke or TIA, hypertension, diabetes mellitus, hyperlipidemia, and CHA₂DS₂-VASc score. Data were analyzed with the SPSS/PC Win package.

Results

A total of 155 patients with ischemic stroke/TIA and known AF before the event were included in the study. The mean age was 78.8 ± 8.9 years and 49% of the subjects were female. Table 1 shows the main clinical features of the overall patients and patients strat-

ified by type of treatment received. The majority of them were hospitalized for first-ever ischemic stroke (74.8%), 30 out of 155 patients were hospitalized for recurrent stroke (19.4%), and the remaining 5.8% had a TIA. Hypertension was the most common risk factor for stroke.

Before stroke, only 3 patients had a CHA₂DS₂-VASc score of 0–1 and were not receiving proper treatment (Fig. 1). A CHA₂DS₂-VASc score >1 was observed in 152 patients (98.1%). Of them, 47 patients were receiving antiplatelet agents and 43 patients were not receiving any treatment. Of 152 patients, 62 (40.7%) were on treatment with oral anticoagulants. Specifically, 34 patients were on DOAC and 28 patients were on VKA. Thirteen patients on DOAC (38.2%) were receiving a nonlabeled reduced dose and 18 patients on VKA (64.3%) had an INR value <2 at admission. Overall, only 34 out of 155 patients (21.9%) were adequately treated according to current guidelines before stroke (Fig. 1). The characteristics of the patients treated or not with oral anticoagulants and the factors associated with the use of anticoagulant treatment are listed in Table 2. Previous stroke or TIA was the only independent predictor associated with the use of anticoagulant therapy in patients with AF (OR 2.93; 95% CI 1.29–6.64). After stroke, no difference in terms of mortality was observed between patients treated or not with oral anticoagulants.

Discussion

In our study, only 21.9% of the patients with known AF were adequately treated according to recent guidelines before a stroke or TIA. Previous stroke or TIA was the only independent predictor of the use of anticoagulant therapy in patients with AF.

Anticoagulation use in AF-eligible patients has been reported to have increased since DOAC became available in clinical practice. In a recent study of 655,000 AF patients with a CHA₂DS₂-VASc score >1, the rate of use of overall anticoagulation increased from 52.4 to 60.7% following the introduction of DOAC [9]. In our study, we specifically focused on

patients hospitalized for acute ischemic stroke or TIA with known AF before the event. We observed that only a quarter of AF patients adequately received oral anticoagulation before stroke. We believe that the high proportion of patients not receiving appropriate therapy observed in our study may depend on a bias of patient selection, as having a stroke is often the result of inappropriate therapy. These findings confirm that underuse or premature discontinuation of anticoagulants is a persistent problem. Their predictable effects without monitoring, their ease of use, and their improved safety profile are some of the advantages of DOAC over VKA that can facilitate patient adherence and increase physician confidence in anticoagulant prescription. Indeed, we cannot exclude that, having included in our study patients from 2013 to 2019, the proportion of patients receiving appropriate therapy may have increased over time. Among patients receiving a reduced dose of DOAC, we found that 65% of the patients were receiving a nonlabeled DOAC reduced dose. There was no indication in 6 out of 13 patients (46%) had of those patients. Inappropriate DOAC prescription is frequent and it is associated with an increased risk of thromboembolic or bleeding events [10]. Underdosing of DOAC is the most common drug-related problem when using the summaries of product characteristics as a reference. In our view, the reasons for underdosing of DOAC are complex. Overall, physicians tend to underdose anticoagulation due to an excessive fear of bleeding in patients with potential contraindications. In our study the only factor that correlated with the likelihood of being anticoagulated was a previous stroke or TIA. This data reflects the reluctance of physicians to prescribe anticoagulation as primary prevention or in patients without additional risk factors. Even a CHA_2DS_2-VASc score >3 could be considered a predictor of the use of anticoagulant therapy in patients with AF, despite it being not significant in our study because of the limited simple size. Finally, the limitations of our study were its small sample size and its single-center nature, which may limit the generalizability of our results.

Conclusion

Only 21.9% of patients hospitalized for a stroke or TIA with known AF were adequately treated according to recent treatment guidelines. After the introduction of DOAC in clinical practice, the number of AF patients who were adequately treated appears to have increased but it is still unsatisfactory. Therefore, it is important not only to improve medical information about the risk of AF and the efficacy of anticoagulants in stroke prevention but also to support an adequate therapy management. Indeed, the creation of a network between hospitals and general practitioners or the increase in the number of physicians eligible to prescribe anticoagulant therapy may be possible strategies to improve the proper use of anticoagulation in patients with AF.
