ABSTRACT: We report the isolation and study of dimers stemming from popular thiazol-2-ylidene organocatalysts. The model featuring 2,6-di(isopropyl)phenyl (Dipp) N-substituents was found to be a stronger reducing agent ($E_{\text{ox}} = -0.8$ V vs SCE) than bis(thiazol-2-ylidenes) previously studied in the literature. In addition, a remarkable potential gap between the first and second oxidation of the dimer also allows for the isolation of the corresponding air-persistent radical cation. The latter is an unexpected efficient promoter of the radical transformation of α -bromoamides into oxindoles.

KEYWORDS: Organocatalysis, N-Heterocyclic Carbenes, Reduction, Radical, Electrochemistry

Thiazol-2-ylidenes **A** (Scheme 1) are synthetic models for the active form of thiamine, a well-known enzymatic

Scheme 1. Thiazol-2-ylidenes **A** and Their Derivatives as Possible One-Electron Transfer Agents in Radical Catalysis or Chain Reactions

cofactor.¹ These stabilized N-heterocyclic carbenes (NHCs) have been used for decades as efficient organocatalysts.^{2–7} They are generated in situ from the reaction of a base and a thiazolium salt. Indeed they cannot usually be isolated, as they readily dimerize. Arduengo et al. reported that the bulky 2,6-di(isopropyl)phenyl (Dipp) N-substituent slows down the dimerization for several hours at room temperature, thus

allowing for the first isolation and characterization of such NHCs, including an X-ray diffraction study.^{8,9} The carbene is already too short-lived for isolation with a slightly smaller 2,4,6-trimethylphenyl N-substituent but could be observed by NMR spectroscopy at 0 °C. Furthermore, traces of Bronsted or Lewis acids catalyze fast dimerization, even for thiazol-2-ylidenes with a high steric hindrance.^{10–12} Therefore, dimers **B** are far more likely to accumulate than carbenes **A** in catalytic processes. Importantly, they react with aldehydes similarly to **A** to afford the key Breslow intermediates. They could be either resting-state reservoirs for **A** or catalysts on their own. Data exist in support and against these hypotheses for the benzoin condensation.^{13–22}

In addition to ionic-type (2-electron) mechanisms, thiazol-2-ylidenes have also recently become privileged organocatalysts for radical transformations of aldehydes.^{23–38} In these reactions, the Breslow-type enolates **C**[–], which result from the condensation of aldehydes with NHCs in basic conditions, are able to undergo spontaneous single-electron transfer (SET) to challenging substrates ($E_{\text{ox}} > -1.6$ V vs SCE).^{59–62} In the absence of aldehydes, free NHCs are milder reducing reactants. For instance, imidazol-2-ylidenes perform stoichiometric reduction of the ferrocenium cation⁶³ ($E = +0.38$ V vs SCE) and the trityl cation⁶⁴ ($E = +0.27$ V vs SCE).⁶⁵ Wang and co-workers recently proposed that thiazol-2-ylidenes **A** could

promote radical transformations in the absence of aldehydes via SET to α -bromocarbonyl compounds and transient formation of radical $A^{\bullet+}$.^{66–69}

Curiously, there is no consideration in the literature of the possible role of dimers **B** in redox NHC-catalyzed processes, although they belong to the large family of dithiadiazafulvalenes, which are known mild electron donors.^{70–72} In addition, electrochemical studies have been limited to electron-poor derivatives with benzo-fused or electron-withdrawing R-substituents.^{73–76} No data are available for a model that is relevant for catalysis. Thus, as part of ongoing efforts to establish a finer mechanistic comprehension of radical NHC catalysis,^{59–62} we underwent the synthesis, isolation, and electrochemical study of dimers **B** of catalytically relevant NHC **A**.

Thiazol-2-ylidenes featuring the 2,6-di(isopropyl)phenyl (Dipp) N-substituent, such as **1a** (Scheme 2), stand out as

Scheme 2. Synthesis of Carbene Dimers 2a–c

polyvalent and efficient organocatalysts for the radical transformation of aldehydes. Therefore, our primary focus was on the dimer **2a** of parent NHC **1a**. We also considered dimer **2b** with a smaller phenyl group in order to probe steric effects and dimer **2c** because thiazol-2-ylidene with a neopentyl (Np) N-substituent found a niche application in radical catalysis for the activation of challenging aliphatic aldehydes.⁷⁷

We synthesized NHC **1a** as previously reported by Arduengo et al.⁸ After 2 days at room temperature in pentane, an orange precipitate was recovered by filtration, washed with pentane, extracted with toluene, and dried under vacuum, affording olefin **2a** in 18% yield. Thiazolium salts **1b,c**·H⁺PF₆[−] were mixed with an excess of NaH and 10% potassium *tert*-butoxide to afford the desired electron-rich olefins **2b,c** in 52 and 28% yield, respectively. The fast reaction likely involves a two-step process including the attack of transient carbene **1** on thiazoliums **1**·H⁺ to afford protonated dimers **2**·H⁺, followed by a second deprotonation. As a matter of fact, when applying this protocol to the Dipp-substituted thiazolium **1a**·H⁺, the hexafluorophosphate salt of **2a**·H⁺ was formed and isolated in 21% yield.

All new products were fully characterized. We obtained suitable single crystals of dimers **2b,c** (Figure 1). A previous X-ray diffraction study showed that **2a** features an almost planar structure in the solid state with a N–C–C–N dihedral angle of 177° and negligible pyramidalization around N atoms (average sum of angles: 359.6°).⁸ In the case of phenyl N-substituted **2b**, the planarity of the olefin pattern is absolute (N–C–C–N dihedral angle: 180°), but lower steric bulk allows a pronounced pyramidalization at the nitrogen atoms (sum of angles: 350.9°). Dimer **2c** also features pyramidalization at nitrogen atoms (sum of angles: 349°) but also a marked trans-bending of the central alkene pattern. It is worth

Figure 1. Solid-state structures of dimers **2a–c**. The structure of **2a** is depicted with a ball-and-stick representation as CCDC 100053 (ref 8) does not provide for thermal factors. Thermal ellipsoids for **2b,c** are set at 50% probability. Selected sides views are also shown. Hydrogen atoms are omitted for clarity; N atoms are highlighted in blue, and S atoms are in yellow.

mentioning that such distortion is not uncommon among NHC dimers: they have been reported for a bis(imidazolidin-2-ylidene)^{78,79} and a methyl N-substituted bis(thiazol-2-ylidene).⁸ Importantly, NMR spectra of the crude products showed the presence of only one isomer. However, whereas **2a,b** are *E*, the *Z*-isomer of **2c** was observed in the solid state. Accordingly, DFT calculations⁸⁰ at the B3LYP-D3BJ/def2-SVP level of theory indicated a slight preference for the *Z* over the *E* configuration for **2c** by 2 kcal·mol^{−1}. Note that the variety of geometrical situations does not significantly affect the central C=C' bond length, which remains almost unchanged within the series (**2a**: 134.4 pm; **2b**: 134.6 pm; **2c**: 134.5 pm).

Cyclic voltammograms of **2a–c** feature two consecutive reversible oxidations, which were attributed to the formation of the corresponding radical cations **2a–c**^{•+} and dication **2a–c**²⁺, respectively (Figure 2). The three dimers are better electron donors ($E_{\text{ox}} < -0.5$ V vs SCE) than previously measured for other dithiadiazafulvalenes ($E_{\text{ox}} \in [+0.4; -0.5$ V]).^{73–76} Olefin **2a** is by far the strongest reducing agent of the series. We attributed its remarkably low oxidation potential of -0.8 V to

Figure 2. Cyclic voltammograms of **2a–c**; 1 mM of each compound in 0.1 M ⁿBu₄NPF₆ acetonitrile electrolyte at 100 mV·s^{−1} rates.

the bulky Dipp substituent, which blocks the amino groups in a planar environment and thus forces them to act as strong +M donors. Munz and co-workers recently proposed that enforced planarity in NHC dimers must also result in radical cations with higher oxidation potentials, thus providing them for thermodynamic protection toward disproportionation.⁸¹ Electrochemical data of **2a–c** obey this trend, as the separation between both redox events roughly correlates with the planarity at the N atom in the solid state (**2a**: $\Delta E = 0.74$ V; **2b**: $\Delta E = 0.35$ V; **2c**: $\Delta E = 0.21$ V).

We attempted the quantitative electrolysis of **2a–c** in acetonitrile. The formation of the corresponding radicals **2a–c**^{•+} could be characterized by UV–vis (see Supporting Information (SI)) and EPR spectroscopies (Figure 3a). As

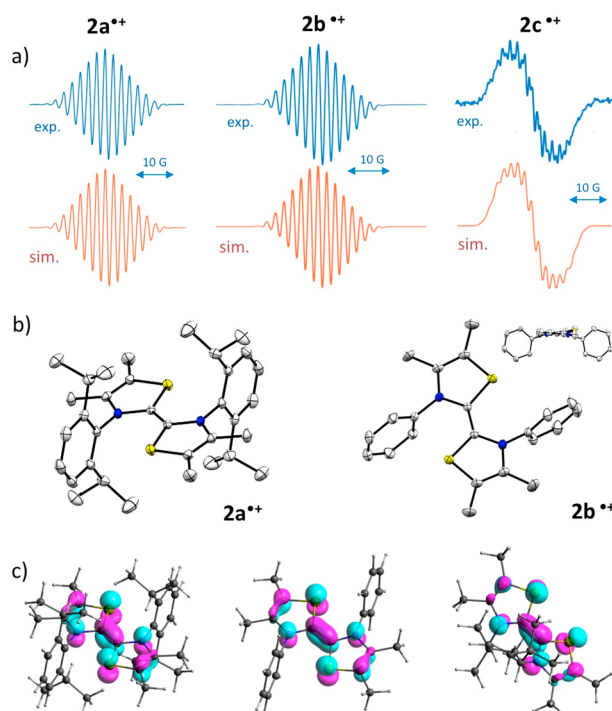

Figure 3. (a) Experimental X-band EPR spectra of **2a–c**^{•+} in acetonitrile at room temperature and respective simulated spectra.⁸² (b) Solid-state structures of [**2a**^{•+}]⁺PF₆[−] and [**2b**^{•+}]⁺PF₆[−] with thermal ellipsoids set at 50% probability. Hydrogen atoms, PF₆[−] anions, and cocrystallized solvent molecule(s) are omitted for clarity. (c) Representations of SOMO of **2a–c**^{•+}.

expected from the geometry of dimers and ΔE values,⁸¹ **2c**^{•+} slowly decomposes. Radicals **2a,b**^{•+} could be synthesized through one-electron oxidation of **2a,b** with NOPF₆ in dichloromethane and isolated in 87 and 51% yield, respectively. Whereas **2b**^{•+} is highly sensitive, we found the sterically protected radical **2a**^{•+} remarkably air-persistent at room temperature, especially in the solid state. Dication **2a**²⁺ was also synthesized from **2a** employing 2 equiv of NOPF₆ (see SI).

Single-crystal X-ray diffraction studies revealed fully planar dithiadiazafulvalene structures for radicals **2a,b**^{•+} (Figure 3b). The central C=C' bond lengths (**2a**^{•+}: 1.403 Å; **2b**^{•+}: 1.391 Å) are about 6 pm longer than in the neutral dimer counterparts **2a,b**. A simple molecular orbital analysis can account for this elongation. Indeed the oxidation process corresponds to the formation of the SOMO of **2**^{•+} (Figure 3c)

by removing an electron from the HOMO of **2**, while both molecular orbitals are bonding combinations of π orbitals of two thiazol-2-ylidene fragments. The DFT-optimized structure of **2c**^{•+} features a less conjugated π -system, with a 30° twist at the central C=C' bond. In radicals **2a–c**^{•+}, the spin density is mainly distributed among N,S and central bridging C atoms (Table 1), with the twisted structure of **2c**^{•+} resulting in a slight transfer of spin density from the heteroatoms to the carbon atoms.

^a E in acetonitrile vs SCE. ^bComputed at the B3LYP-D3BJ/def2-SVP level of theory.

The large potential gap between the first and second oxidations of **2a** ($\Delta E = 0.74$ V) indicates that it must behave as an efficient one-electron donor. It also stands out among bis(thiazol-2-ylidenes) as a remarkably strong reducing olefin ($E(\mathbf{2a}^{\bullet+}/\mathbf{2a}) = -0.80$ V vs SCE). Overall, these data suggest that dimer **2a** might not be innocent in radical transformations allegedly involving the popular NHC **1a** as a catalyst. For instance, recent works from Wang et al. attracted our attention. Methodological studies showed that α -bromoisobutyramides, such as **3** (see Table 2) can be activated with NHC radical catalysis to afford oxindoles, and free thiazol-2-ylidene **1a** was proposed as a key single-electron donor.⁶⁶

In order to evaluate the reducing ability of thiazol-2-ylidenes, we considered their precursors **1a–c**•H⁺. Their cyclic voltammograms feature an irreversible reduction wave around –1.5 V, which corresponds to an EC process^{83,84} generating free carbenes **1**, through the formation of radical **1**•H[•], followed by the fast loss of H[•]. The reoxidation wave allowed thiazol-2-ylidenes **1a–c** to feature oxidation potentials E_p^{ox} (**1**/**1**^{•+}) higher than –0.2 V vs SCE (see SI).

Not only is thiazol-2-ylidene **1a** a very weak reducing agent, but the NHC is also prone to fast dimerization in the reaction conditions. Therefore, we naturally hypothesized that olefin **2a** was the relevant electron donor in the transformation of **3** into oxindole **4**, and we ran a few control experiments (Table 2). We first reproduced results from the literature⁶⁶ employing [**1a**•H⁺]PF₆ as a precatalyst (entry 1). Oxindole **4** was formed in 62% conversion (reported: 63%). Phenyl N-substituted **1b**•H⁺ was less performant (entry 2) and **1c**•H⁺ barely promoted the reaction (4% conversion, entry 3). As expected, the corresponding dimers **2a–c** gave similar or higher conversions (entries 4–6).

The reduction potential of ethyl α -bromoisobutyrate **5**, which is electronically similar to **3**, is reported to be E_p^{red} (**5**/**5**^{•–}) = –0.77 V in DMSO.³⁵ This value would support a spontaneous SET from **2a** (E_{ox} = –0.80 V) to **5**. However, α -bromoisobutyryl derivatives may be in fact more challenging to reduce than previously proposed. Indeed, we found a different value, E_p^{red} (**5**/**5**^{•–}) = –1.89 V in acetonitrile (see SI), which prompted us to measure E_p^{red} (**3**/**3**^{•–}) which was found at to be –1.94 V vs SCE in acetonitrile. Even more, we tested hexafluorophosphate salts of **2a,b**^{•+} as catalysts (entries 7 and 8). Surprisingly, the radical cations were more efficient than the corresponding electron-donating olefins **2a,b**. These data suggest that the hypothesis of a simple SET process is not valid.

In conclusion, bis(thiazol-2-ylidene) **2a**, stemming from the popular NHC organocatalyst **1a**, presents three stable redox states. The bulky Dipp N-substituent forces planar geometries, thus resulting in an unusually low oxidation potential and a comparatively high second oxidation potential, allowing for the isolation of air-persistent radical **2a**^{•+}. Olefin **2a** is not strong enough to compete as a reducing agent with Breslow-type enolates. However, it remains a potential electron donor, which can interfere in radical reactions that are allegedly catalyzed by **1a** and does not involve aldehyde derivatives as substrates. In the specific case of the activation of α -bromoisobutyramides, we unexpectedly found that radical **2a**^{•+} is the most efficient redox form as a catalyst. This surprising result suggests that the NHC derivatives are unlikely to promote this radical reaction through a simple SET, as initially proposed. We are actually undergoing further experimental and theoretical studies, in an attempt to decipher and better understand such process.
