Objective: Most mental disorders are diagnosed and treated in general practice. Psychometric tests may help the general practitioner diagnose and treat mental disorders like dementia, anxiety, and depression. However, little is known about the use of psychometric tests in general practice and their impact on further treatment. We aimed to assess the use of psychometric tests in Danish general practice and to estimate whether variation in use is associated with the provided treatment and death by suicide in patients.

Methods: This nationwide cohort study included registry data on all psychometric tests performed in Danish general practice in 2007–2018. We used Poisson regression models adjusted for sex, age, and calendar time to assess predictors of use. We used fully adjusted models to estimate the standardized utilization rates for all general practices.

Results: A total of 2,768,893 psychometric tests were used in the study period. Considerable variations were observed among general practices. A positive association was seen between a general practitioner's propensity to use psychometric testing and talk therapy. Patients listed with a general practitioner with low use had an increased rate of redeemed prescriptions for anxiolytics [incidence rate ratio (95% confidence interval):1.39 (1.23;1.57)]. General practitioners with high use had an increased rate of prescriptions for antedementia drugs [1.25 (1.05;1.49)] and first-time antidepressants [1.09 (1.01;1.19)]. High test use was seen for females [1.58 (1.55; 1.62)] and patients with comorbid diseases. Low use was seen for populations with high income [0.49 (0.47; 0.51)] and high educational level [0.78 (0.75; 0.81)].

Conclusion: Psychometric tests were used mostly for women, individuals with a low socioeconomic status, and individuals with comorbid conditions. The use of psychometric tests depends on general practice and is associated with talk therapy, redemptions for anxiolytics, antedementia drugs, and antidepressants. No association was found between general practice rates and other treatment outcomes.

Keywords: psychometric tests, registries, general practice, mental disorders, treatment variation

Plain Language Summary

- Most mental disorders are diagnosed and treated in general practice. They are linked with adverse health outcomes; other mental disorders, somatic disorders, and death by suicide.
- Psychometric tests can be used in the diagnostic process and help monitor the treatment.
- This register-based study investigates variations in the use of psychometric tests in Danish general practice. It also estimates whether such variations affect the treatment of different patient populations and their outcomes, eg referral to secondary care and death by suicide.
- The study shows that the use of psychometric tests varies between general practices and is used mostly for women, patients with low socioeconomic status or comorbid conditions.
- A positive association was seen between a general practitioner's propensity to use psychometric testing and talk therapy.
- High rates of test use were associated with more prescriptions for antedementia drugs and antidepressants, whereas low rates were associated with more prescriptions for anxiolytics.
- We found no association for antipsychotics, psychological/psychiatric treatment, or suicide.

Introduction

The majority of patients with mental disorders are diagnosed and treated in general practice.¹ In Denmark and many other countries, general practitioners (GPs) act as gatekeepers to secondary care and refer patients in need of specialized treatment. Thus, there is a need for ensuring a reliable diagnostic process and identifying optimal treatment regimens, eg, talk therapy, medication treatment, and outpatient care. Mental disorders are linked with adverse health outcomes, such as other mental disorders, somatic disorders, and death by suicide.^{2–5} Psychometric tests (PTs) are instruments to aid the GP during the diagnostic process and help monitor treatment outcomes.^{6,7} PTs may serve as screening devices, diagnostic instruments, or rating scales for measuring disease severity. Danish clinical guidelines recommend the use of PTs for a range of disorders, eg, dementia, anxiety, and depression,^{6–8} and the GP is required to have performed a PT when referring a patient with depression to a psychologist. Since 2007, Danish GPs have used a specific service code and received remuneration when using clinically recognized PTs. A recent clinical trial showed that systematic use of a depression-related PT did not increase the diagnostic precision compared with usual clinical assessment in Danish general practice.⁹ Variation in health care and their influence on treatment outcomes are well documented.^{10,11} A recent Danish study found an excess variation between Danish general practices in terms of the chronic care services provided, eg, talk therapy.¹² However, little is known about the use of PTs in general practice. Therefore, we wanted to explore the rate of PT use in general practice by using methods applied for ranking health service providers in a broad unselected national setting.^{13,14}

This study aimed to investigate the variation between general practices in the use of PTs, including variation related to patient characteristics, practice type, and geographical region. Further, this study aimed to explore whether variation in PT use modified the patients' rate of received talk therapy sessions, medication treatment for mental disorders (antidepressants, antipsychotics, antedementia drugs, and anxiolytics), referral to psychological or psychiatric treatment in the primary and the secondary sector, and death by suicide.

Methods

Setting and Participants

To explore time trends in the use of PTs in Danish general practice, we used Danish national registries to conduct a cohort study including all Danish residents above 18 years of age who were listed with a general practice in 2007–2018. We chose December 31, 2018, as the endpoint as this was the last date of fully available data. The majority (98%) of the Danish population is listed with a specific general practice.¹⁵ We also used information from the patient list database, which holds monthly updated information on the patient population for each provider.¹⁶ In a sub-cohort based on data for only 2017–2018, we investigated the variation in PT use among Danish general practices and associated patient-related treatment outcomes, regional variation, and variation in PT use for different subgroups of patients. Using the unique personal identification number assigned to all Danish residents at birth or immigration, we linked information across the included registers.¹⁷ In both cohorts, we restricted to “active” general practices, ie, clinics with at least 500 patients affiliated throughout a calendar year.

Psychometric Tests

From the Danish National Health Insurance Service Register (NHISR), we obtained data on contacts to general practice. This register holds information on all contacts to GPs based on administrative data (used for remuneration purposes) on the services provided.¹⁵ All consultations recorded in the register include information on provider number, personal identification number (patient), date, time and type of consultation, and provided service. PTs were identified through the service code 2149 for all general practice specialty codes (80–89). Only PTs performed in the daytime on weekdays were included.

Outcomes

The NHISR holds information on talk therapy performed by the GP and information on publicly subsidized psychological and psychiatric treatment (following GP referral), which was identified through specialty codes 63

and 24, respectively. Psychologist contacts were restricted to referral for depression or anxiety. Redemption of prescriptions for antidepressants, antipsychotics, anxiolytics, or antimentia drugs was identified in the Danish National Prescription Registry (DNPR) through ATC codes *N06A* (not including *N06AX12*), *N05A*, *N05B*, and *N06D*, respectively. DNPR holds information on all prescriptions redeemed at any pharmacy in Denmark.¹⁸ Contacts with public mental health hospitals were identified in the Danish National Patient Register (NPR), which holds continuously updated information on all contacts to the secondary health-care sector.¹⁹ Using the Danish Register of Causes of Death,²⁰ we identified all deaths by suicide in the study period by using the ICD-10 codes X60–X84 and Y87 ([Supplementary Table 4](#)).

Calendar Time

Calendar time was divided into categories of year and season. Season was categorized into four groups: 1 (December, January, and February), 2 (March, April, and May), 3 (June, July, and August), and 4 (September, October, and November).

Sociodemographic Variables

Information on sex and age was extracted from the Danish Civil Registration System (DCRS).¹⁷ The DCRS contains continuously updated information on date of birth, immigration and emigration, sex, and vital status of all Danish residents.

Socioeconomic Status

Information on the highest attained education level, income, cohabitation status, and region of residence was obtained from the annually updated registers at Statistics Denmark.²¹ We divided educational status into four categories based on the United Nations Educational, Scientific, and Cultural Organization's International Standard Classification of Education (0–10 years, 11–15 years, ≥16 years, or unknown).^{22,23} Household income was divided into decile sets by year; negative income was partly explained by business loss under self-employment, and these cases were put in a separate category. Cohabitation status was divided into single, living with a partner, or married ([Supplementary Table 5](#)).

Comorbidity

Data on comorbidity originated from NPR and DNPR. Included data were selected through an algorithm developed by Prior et al. This algorithm identifies 39 disorders in the circulatory system, endocrine system, pulmonary and respiratory system, gastrointestinal system, urogenital system, musculoskeletal system, hematological system, neurological system, cancers, and mental health conditions treated in both primary and secondary care ([Supplementary Table 6](#)).²⁴

GP Information

Information on each general practice was based on two data sources: the Patient List Database and the Danish National Provider Registry comprising information on all public health providers.^{16,25} This enabled us to identify type of practice (solo practice or non-solo practice), number of GPs employed, and size of patient population. It also allowed us to identify the geographical region of each general practice based on the most prevalent region of residence in the patient population.

Statistical Analysis

Use Over Time

To provide a crude overview of PT use during the entire follow-up period from 1 January 2007 through 31 December 2018, we calculated the PT rate for each GP as the total number of PTs performed over the general practice affiliated person-time in that year. The rates were presented as per 1000 person-years ([Table 1](#)).

In the sub-cohort based on data from 1 January 2017 through 31 December 2018, we assessed the characteristics associated with PT use and the variation in PT use between general practices ([Table 2](#)).

Table 1 PT Use in Danish General Practice in 2007–2018

Year	Median Rate (IQI) ^c	Person-Years	PTs ^b	General Practices (no PTs) ^a
2007	18 (6; 41)	4,970,025	158,673	2235 (151)
2008	21 (8; 48)	4,951,283	181,511	2182 (103)
2009	25 (9; 50)	4,903,790	194,858	2148 (116)

Notes: ^aAdjusted for age, sex, and calendar period. ^bNumber of PTs differs between Table 1 and Table 2 due to minor differences in the definition of "active" general practices in the two cohorts. ^cRates are calculated as number of PTs per 1000 person-years.

Abbreviations: PT, psychometric test; IRR, incidence rate ratio; CI, confidence interval.

Predictors of PT Use

First, we wanted to investigate the crude association between patient variables and general practice variables and the use of PTs. This was done by mutually adjusting for sex, age, year, and season. As the number of PTs is a discrete non-negative count variable, we used generalized linear models with a log-link assuming Poisson distributed errors (ie, Poisson regression) and each person's at-risk time as the offset to analyze the number of PTs. This approach yielded incidence rate ratios (IRRs). To consider apparent clustering at general practice level, we used cluster-robust variance estimation.²⁶ All estimates with 95% confidence intervals (CIs) (Table 2).

Variation Among General Practices

To assess the variation in PT use between general practices, we calculated the standardized PT rate (sPT rate) for each general practice in the study population. This was done in several steps. First, we used a Poisson regression model, which was fully adjusted for all non-provider variables, ie, age, sex, year, season, cohabitation, immigration status, educational

status, income, and comorbidity, to predict the expected number of psychometric tests per person during follow-up. Covariates for the prediction model were selected prior to the analyses. This enabled us to calculate the number of PTs that we would expect a given general practice to perform during follow-up, given its patient population. Second, we counted the observed number of PTs performed for each general practice and compared this number with the expected number of PTs in an observed over expected (OE) ratio. Finally, we calculated the crude overall national PT rate during follow-up and multiplied this rate with the OE ratio, which yielded the sPT rate for each general practice. The sPT rate was depicted graphically, ordered from the lowest rate to the highest rate. To comply with the legal data regulations on anonymity, all practice rates were combined into clusters of five practices. The mean rate within each cluster was plotted. This was done for all practices and for the general practice-related subgroups: region, number of doctors, size of patient population, and solo practice (or not). We estimated the number of doctors and the size of the patient population in a specific general practice for a given time period by using the frequency weighted average for that period (Table 3 and Figure 1). To test for excess variation between general practices, we first fitted a mixed Gaussian model with a random component for general practice and afterward fitted a Gaussian model without the random component and performed a likelihood ratio test of the hypothesis of no random component for general practice.²⁷

Treatment Outcomes and Suicide

To investigate the association between being affiliated with a general practice with a certain OE ratio and being referred to a certain treatment regimen in the primary or secondary health-care sectors and the risk of suicide, we randomly divided the study population into two groups: a training sample (70%) and a test sample (30%). The division was made in each general practice to ensure enough observations per general practice to be able to analyze the association for the time period when the OE ratio was calculated. In the training sample, we once again fitted the full model and calculated the OE ratio for each general practice. In the test sample, we used the OE estimate (categorized into decile sets) as an independent variable in regression analyses. The seventh decile group was considered the reference category since this group comprised the empirical OE ratio of 1 and thus had a PT rate as expected based on the model. For the four medication outcomes, we conducted two separate types of analyses. In one type, we looked at the number of redeemed prescriptions. In the other type, we restricted to

Table 3 General Practice Characteristics and Standardized PT Rates

Variable	Level	N Practices (%)	Median sPT (IQI)
Region	North Denmark Region	142 (8.7%)	45 (21; 74)

never users and investigated the risk of a first-time redemption. The analyses of prescriptions for antedementia drugs were restricted to individuals above 75 years of age. The other outcomes considered were number of talk therapy sessions, number of contacts with publicly subsidized psychological or psychiatric treatment, number of contacts with public mental health hospitals, and the risk of death by suicide. These analyses were conducted in four prespecified nested adjustment models. Model 0 (m0) was unadjusted. Model 1 (m1) was adjusted for age, sex, and calendar time. Model 2 (m2) was adjusted as m1 + immigration status, cohabitation status, educational level, income, and somatic comorbidities. Model 3 (m3) was adjusted as m2 + mental health conditions. In the analyses of antidepressants, antipsychotics, and antedementia drugs, m3 did not include the variables for psychological distress, bipolar disorder, and dementia, respectively, due to overlap in the coding definitions. M3 was considered the main model (Figure 2). To assess differences between combinations of OE group and train and test samples, we calculated the proportion of risk time spent for each variable used in the regression analyses.

In all analyses, all variables, except for sex and immigration status, were considered to be time-dependent, ie, a person being diagnosed with a specific disease during the follow-up period contributed with risk time in the no-disease category until the date of diagnosis, whereafter this person contributed with risk time in the disease category. In the sub-analyses, we restricted to persons below 75 years of age.

All analyses were performed with Stata, version 17.

Results

Use Over Time

Throughout the study period, a total of 2,768,893 PTs were used in a study population of 57.52 million person-years. From 2007 to 2012, a rise in the use was observed from about 160 thousand PTs in 2007 to about 260 thousand PTs in

Model m3

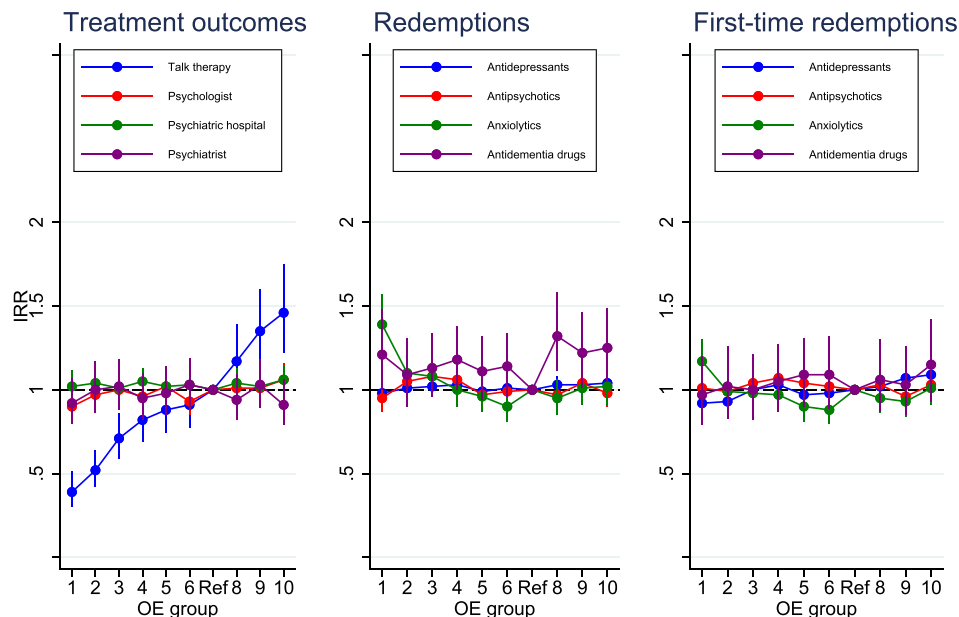

Figure 2 IRRs of treatment regimens and medicine redemption by decile groups of the observed over expected ratio.

2018 (Table 1). The median PT rate rose from 18 PTs per 1000 person-years in 2007 to 37 PTs per 1000 person-years in 2012. Thereafter, the rate plateaued. Throughout the study period, a steady variation in PT use was observed among GPs, with an interquartile range from 35 up to 53. Among eligible general practices, 6.8% used no PTs in 2007; this number decreased to 2.1 in 2018 (Table 1).

Predictors of PT Use

Sociodemographic Variables

Among the sociodemographic variables, we observed that women had 1.58 times higher PT rate than men (95% CI) (1.55; 1.62) (Table 2). The rate varied over age groups, with 1.32 times higher rate (1.23; 1.42) among those aged ≥ 85 years compared with those aged 18–24 years. Those aged 65–74 years had a 39% lower rate (0.58; 0.64) than those age 18–24 years. Compared with GPs in the North Denmark Region, GPs in the Central Denmark Region had the highest relative PT rate, IRR 1.20 (0.98; 1.45), whereas GPs in Region Zealand had the lowest, IRR 0.82 (0.67; 1.01).

Calendar Period

The summer season had the lowest rate of PTs, 16% lower than the winter season, whereas the fall season had the highest rate, 13% greater than the winter season (Table 2).

Socioeconomic Characteristics

Among the socioeconomic variables, being married or living with a partner, having completed a higher education, having a high income, or being an immigrant were negatively associated with PT use compared with their reference groups. For example, the PT rate was 51% lower among persons with an income in the highest category compared with persons in the lowest category (49%; 53%) (Table 2).

Comorbidity

Most disorders were positively associated with PT use compared with not having that disorder (Table 2). This was most apparent for mental health conditions. For example, those registered with psychological distress had 3.91 times higher PT rate than those without (3.80; 4.03), and those registered with a mood, stress-related, or anxiety disorder had 3.08 times

higher PT rate (3.01; 3.17) compared to those without. In addition, an increased PT rate was observed among the somatic disorders, eg, stroke, which resulted in a 50% increased rate (1.46; 1.55).

Variation Among General Practices

After adjustment for potential differences in the patient population between general practices, we found an excess variation in the sPT rates between the included practices (Chi-square=28294.05, p-value <0.0001) (Figure 1A). The ranked sPT rates across all practices, divided according to practice characteristics, are depicted graphically in Figure 1A–E. Among all practices, the (pooled) practice in the 10th percentile had an sPT rate of 12 PTs per 1000 patient-years, whereas the corresponding (pooled) practice in the 90th percentile had an sPT rate of 115 PTs per 1000 patient-years. In terms of the interquartile range (IQR) of the sPT rates, we found a greater IQR between the small practices compared with the large ones (Table 3 and Figure 1C–E). For example, the IQR was 58 for practices with 500–1599 patients affiliated and 37 for practices with more than 4800 patients affiliated. The practice type also influenced the variation; an IQR of 58 was found for solo practices, and an IQR of 38 was seen for other types of practices. The median level of sPT rates was highest in the Central Denmark Region [median sPT interquartile interval (IQI): 49 (29; 81)] and lowest in the Region Zealand [median sPT (IQI): 35 (20; 61)].

Treatment Outcomes and Suicide

The tendency among general practices to use PTs and offer talk therapy was associated in a dose–response manner. Compared with the seventh decile group, the tenth decile group showed an elevated rate [1.46 (1.22; 1.75)], whereas the first decile group showed a lowered rate [0.39 (0.30; 0.51)] (Figure 2, Supplementary Table 1). No apparent associations were found between PT tendency and publicly subsidized psychological or psychiatric treatment, contacts with psychiatric hospitals, treatments with antipsychotics, and the risk of suicide. However, patients listed with a general practice in the first decile group had an increased rate of anxiolytics use compared with the reference group. The difference persisted when we restricted to never users and first-time redemptions. Likewise, we found that patients listed with a general practice with a high PT tendency had an increased rate of redeemed antedementia drug prescriptions compared with the reference group. Though, an increased rate was also found for the group in the first and fourth deciles, the differences disappeared when we restricted to first-time users. No associations were found for a number of antidepressant redemptions. However, when restricting to first-time redemptions, we found an increased rate in patients listed with GPs with a high PT tendency. A similar picture was seen for persons younger than 75 years of age, except for antedementia drugs, which were infeasible (Supplementary Figure 1, Supplementary Table 2). The groups comprising combinations of OE group and training and test samples were similar in terms of the variables used in the analyses. However, the first OE decile group consisted of more men than women, and they tended to be older compared to the other decile groups (Supplementary Table 3).

Discussion

Key Results

In this nationwide register-based explorative cohort study, we observed that the use of PTs has become more frequent among Danish GPs since 2007 when the service code for PTs was introduced. Increased PT rates were seen for women, low income, low educational level, and comorbid disorders. However, an excess variation was seen in PT use among the included general practices. PT use was most common in the Central Denmark Region and least common in Region Zealand. A positive association was observed between the tendency of a general practice to use PT and the tendency to offer talk therapy. Patients listed with a general practice with low PT use had an increased rate of redeemed prescriptions for anxiolytics medication. Patients listed with a general practice with high PT use had an increased rate of redeemed prescriptions for antedementia drugs and first-time antidepressants. However, the difference for antedementia drugs disappeared when we restricted to never users and first-time redemptions. No apparent associations were observed for psychological and psychiatric treatment, redemptions of antipsychotics, and suicide.

Comparison with Other Studies

To our knowledge, this is the first study to investigate the variation in the use of PTs in general practice. A recent Danish clinical study on the value of systematic psychometric testing, ie, no variation in use, did not find the diagnosis of depression to be more precise when based on psychometric testing compared with usual clinical assessment.⁹ This finding was somewhat confirmed in this study, as we found no significant difference between groups with varying propensity for PT use for most of the investigated treatment outcomes. The finding of increased variation in the provided services has also been reported in other studies, with indications that some variation is non-negligible due to derived outcomes, such as the need for immediate identification and treatment of patients at risk of suicidal behavior after the loss of a loved one.^{12,28,29}

Strengths and Limitations

The Danish registers enabled us to combine health data, administrative data, and socioeconomic and demographic data at the personal level with no loss to follow-up. The continuous update of health databases allowed for construction of time-dependent variables and reduced the risk of potential biases from reverse causation and conditioning on the future, which might have introduced immortal time bias. The use of service codes enabled us to identify whenever a PT had been used, by which provider number, and to whom it was given. However, the NHISR held no information on the reason for contact with the GP (other than provided by the service code). For example, it could not be distinguished whether a PT had been used for dementia, depression, or anxiety. Hence, an important limitation was the lack of access to diagnoses in primary care. However, this limitation was addressed by the use of a multimorbidity algorithm incorporating disease-specific medication.²⁴ In sub-analyses, we restricted to a population under the age of 75 years to reduce the potential risk of selection bias from the use of dementia-indicated PTs, and we found no apparent differences compared with the overall results.

When computing the observed over expected ratio, small general practices with a small number of expected PTs had an inherent ability to be noisier than large practices. One more or one less PT performed will move the ratio more substantially for practices with few numbers of expected PTs compared with those with large numbers of expected PTs. The finding that small practices had greater ratio variations compared with large practices could result from this. However, this potential limitation was alleviated by restricting to practices with at least 500 listed patients. Another limitation of NHISR was that it provided only data on practice level. Thus, if a practice comprised several GPs, the sPT rate for that provider number would be a weighted average of all the GPs' sPT rates.

To standardize PT rates, it is crucial to choose the correct variables and the right predictors for PT use. However, not all predictors were available due to the lack of diagnosis data from general practice. Yet, as shown in [Table 2](#), the a-priori chosen variables do appear to be associated with PT use. Still, residual confounding and unmeasured confounding cannot be ruled out. For the analyses regarding [Figure 2](#), we presented the fully adjusted estimates from m3. This model might have overadjusted the association of interest. Thus, the presented estimates might be conservative. Nevertheless, the estimates from m0, m1, and m2 did not alter the conclusions.

Interpretation

We found a higher PT rate among patients with a low socioeconomic status, eg, low education and low income. Higher prevalence of mental disorders has previously been reported in this group.³⁰ The observed high PT rate for comorbid disorders was expected because of the association between physical and mental disorders.² We also found a lower PT rate among immigrants, which could be explained by a limited number of available PTs in other languages than Danish. The low rate in the summer is likely to be related to the holiday period with fewer open hours in general practice.

Variation in the services provided by Danish GPs has previously been investigated by examining variations in chronic care consultations, including talk therapy sessions.¹² In our study, we found a clear positive dose–response association between PT rate and talk therapy rate. Specifically, we observed the greatest variation in the propensity for PT use among the smallest practices. One reason for this could be lack of communication with other peers, but random variation due to smaller sample sizes might also be an explanation.

The observation that some general practices had a different PT rate than expected (based on the standard rate) does not per se mean that they need to change their rate, since the standard rate is not a gold standard.³¹ When we categorized on propensity for PT use, minor differences were observed for treatment-related outcomes. We found that patients listed with a GP with low PT use had elevated rates of anxiolytics compared with those with a standard rate of PT use; this could indicate that some GPs have a different attitude towards diagnosis and treatment of mental disorders or that the characteristics of their patient populations vary significantly, which might explain the predisposition towards anxiolytics medication. One should bear in mind that these exploratory analyses cannot give a causal explanation, and some differences between the patient populations were evident.

As mentioned above, unmeasured confounding on the person level cannot be ruled out. The same holds for indication for PT use. Thus, the (excess) variation between GP-related sPT rates might be contaminated. We tried to address the lack of information on indicated PT use by including redemptions for antidementia drugs, and we saw that patients listed with a GP with a high tendency for PT use had a higher rate of redemptions for these drugs. However, when we restricted to those under age 75 years, the differences remained for talk therapy and anxiolytics redemptions.

Generalizability

In Denmark, the healthcare system is mainly publicly funded, and all residents have access to universal healthcare. As Danish GPs are remunerated for using clinically recognized PTs, GPs have a financial incentive to use PTs. Therefore, we would expect the differences to be more pronounced in payment-based health-care systems.

Conclusion

PTs are common tools in Danish general practice. PTs are mostly used for women, those with a low socioeconomic status, and comorbid conditions. The use of PTs depended on GP affiliation and was positively associated with use of talk therapy. High sPT rates were associated with high redemption rates for antidementia drugs and incident redemptions for antidepressants, whereas low sPT rates were associated with high redemption rates for anxiolytics. The tendency to use PTs was not associated with psychological or psychiatric treatment or antipsychotics, or suicide.

Data Sharing Statement

Due to restrictions related to Danish law and protection of patient privacy, the data used in this study can only be made available through a trusted third party, Statistics Denmark, which holds the data records for this study. Research groups based in a Danish scientific setting can be authorized to work with data within Statistics Denmark. Access to individual scientists inside and outside of Denmark may be authorized upon request directed to Statistics Denmark.

Ethics Statement

The study required no approval from the Committee on Health Research Ethics in the Central Denmark Region as it was based on register data, and all patient information was anonymized and de-identified prior to analysis by Statistics Denmark.

Acknowledgments

The authors would like to thank Lone Niedziella for language editing, and Statistics Denmark for providing the data infrastructure.

Funding

HSP was funded by an unrestricted grant from the General Practice Research Foundation of the Central Denmark Region (Region Midtjyllands Praksisforskningsfond). AP was funded by the Novo Nordisk Foundation (grant no. NNF18OC0031194). The funders had no role in the study design, data collection, data analysis, data interpretation, or writing of the paper.

Clinical Epidemiology

Dovepress

Publish your work in this journal

Clinical Epidemiology is an international, peer-reviewed, open access, online journal focusing on disease and drug epidemiology, identification of risk factors and screening procedures to develop optimal preventative initiatives and programs. Specific topics include: diagnosis, prognosis, treatment, screening, prevention, risk factor modification, systematic reviews, risk & safety of medical interventions, epidemiology & biostatistical methods, and evaluation of guidelines, translational medicine, health policies & economic evaluations. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use.
