## ABSTRACT

**Introduction** Early reports highlighted racial/ethnic disparities in the severity of COVID-19 seen across the USA; the extent to which these disparities have persisted over time remains unclear. Our research objective was to understand temporal trends in racial/ethnic variation in severity of COVID-19 illness presenting over time.

**Methods** We conducted a retrospective cohort analysis using longitudinal data from Cedars-Sinai Medical Center, a high-volume health system in Southern California. We studied patients admitted to the hospital with COVID-19 illness from 4 March 2020 through 5 December 2020. Our primary outcome was COVID-19 severity of illness among hospitalised patients, assessed by racial/ethnic group status. We defined overall illness severity as an ordinal outcome: hospitalisation but no intensive care unit (ICU) admission; admission to the ICU but no intubation; and intubation or death.

**Results** A total of 1584 patients with COVID-19 with available demographic and clinical data were included. Hispanic/Latinx compared with non-Hispanic white patients had higher odds of experiencing more severe illness among hospitalised patients (OR 2.28, 95% CI 1.62 to 3.22) and this disparity persisted over time. During the initial 2 months of the pandemic, non-Hispanic blacks were more likely to suffer severe illness than non-Hispanic whites (OR 2.02, 95% CI 1.07 to 3.78); this disparity improved by May, only to return later in the pandemic.

**Conclusion** In our patient sample, the severity of observed COVID-19 illness declined steadily over time, but these clinical improvements were not seen evenly across racial/ethnic groups; greater illness severity continues to be experienced among Hispanic/Latinx patients.

## INTRODUCTION

The emergence and rapid spread of the novel SARS-CoV-2 have exposed and exacerbated racial and ethnic health disparities across the country.[1–5] Prior analyses of disparities in COVID-19 illness have not fully accounted for variations in underlying comorbidities or assessed the extent to which severity of COVID-19 clinical presentations is evolving over the course of the pandemic.[6–11] There is strong reason to suspect that severity of

## What this paper adds

► The COVID-19 pandemic has disproportionately affected minority communities. Datafrom early in the pandemic demonstrated worse outcomes, particularly amongAfrican Americans.

► COVID-19 severity of illness among non-Hispanic blacks initially improved, however, but is showing signs of returning.

► Severity of COVID-19 illness among the Hispanic/Latinx population remained higher than non-Hispanic whites during most of the pandemic and shows signs of worsening.

► COVID-19 severity of illness among minority populations has changed during the course of the pandemic, but has been persistently worse among Hispanic/Latinx patients. Growingdisparities in severity of illness may reflect decreased ability of the minority population to limit exposure to the virus, aswell as obtaining less benefit from novel treatments for COVID-19.

illness is not only changing over time but also varying by race and ethnicity—at least partly due to the dynamic interplay between public health efforts to limit disease spread, improvements in medical therapies, and racial/ethnic clustering of socioeconomic factors such as essential employment status, neighbourhood infrastructure and trust in the medical system.[12] To better understand racial/ethnic variation in how COVID-19 illness severity is changing over time, while accounting for the effects of pre-existing conditions and socioeconomic factors, we conducted multivariable-adjusted temporal trends analyses using longitudinal data collected from our healthcare system, which serves as a primary high-volume clinical centre for treating COVID-19 illness affecting the diverse urban population of the greater Los Angeles County.

## METHODS

### Study population

In this retrospective cohort study, we identified all patients admitted to the hospital with confirmed SARS-CoV-2 infection in our large multisite health system based in Los Angeles, California (Cedars-Sinai Medical Center, CSMC), from 4 March through 5 December 2020. As the largest non-profit hospital in western USA, CSMC serves a catchment area of >1.8 million people, with over a quarter million inpatient hospital days for admitted patients, >90 000 emergency department visits and nearly 800 000 outpatient appointments each year. All laboratory testing for SARS-CoV-2 were performed using reverse transcriptase PCR of extracted RNA from nasopharyngeal swabs at the Los Angeles Department of Public Health from 4 March to 21 March 2020 and thereafter at the CSMC Department of Pathology and Laboratory Medicine. A limited number of patients (1.0%) received SARS-CoV-2 testing at an outside facility, and documentation of a positive test result was reviewed by medical staff and considered comparable for accuracy.

### Data collection

We curated demographic, clinical and outcomes data from the electronic health record (EHR) and confirmed all key variables with manual adjudication. We defined race and ethnicity membership as follows: Hispanic/Latinx ethnicity (all races), non-Hispanic black (NHB), Asian/Pacific Islander, non-Hispanic white (NHW) and other (including individuals with multiple races listed). We used data from the American Community Survey 2019 to calculate neighbourhood socioeconomic status (SES) for each patient census tract based on the Agency for Healthcare Research and Quality (AHRQ) SES index,[13] which includes measures of unemployment, household income, property value, poverty level and educational attainment. We mapped patients to a census tract using their primary address listed in the EHR.

To capture relative comorbid status at the time of presentation to medical care, the Elixhauser Comorbidity Index (ECI) score, using van Walraven weighting,[14] was calculated for all patients based on the International Classification of Diseases-10 codes present prior to or at the time of initial presentation for COVID-19. Hospitalisation characteristics including length of stay, admission to an intensive care unit (ICU), intubation and in-hospital death were ascertained from time stamps recorded for admission, unit transfers and discharge. Interventions such as intubation were identified through time-stamped orders in the EHR and verified by manual chart review.

### Clinical outcomes

Our primary objective was to evaluate temporal trends of COVID-19 severity of illness among hospitalised patients by race and ethnicity. Hospitalised patients, rather than all patients diagnosed with COVID-19, were selected given the known variation in rates of presentation to care over time, particularly in relation to periodically imposed lockdowns that may have influenced patterns of detection and diagnosis of the milder forms of COVID-19 illness. We defined severity of illness as an ordinal variable, based on a modified core outcome measure scale[15]: 0=required hospitalisation but no ICU or intubation (least severe); 1=required hospitalisation and ICU but no intubation; and 2=required hospitalisation, ICU, and intubation or death (most severe).

### Statistical analysis

We summarised demographic and clinical characteristics using mean and SD for continuous variables and counts with percentages for categorical variables. We used $\chi^2$ test and one-way analysis of variance to compare demographic and clinical characteristics, by racial/ethnic subgroups, within four discrete time periods. Time periods were calculated based on quartiles of the cumulative distribution of daily COVID-19 admissions (in our sample) to account for variations in incidence over the course of the pandemic: period 1, from 4 March to 7 May; period 2, from 8 May to 14 July; period 3, from 15 July to 20 October; and period 4, from 21 October to 5 December. We conducted multivariate ordinal logistic regression to examine the association between race/ethnicity and severity of illness adjusting for age, sex, ECI and SES index both overall and for each distinct time period. We fit models using restricted cubic splines with seven knots to account for dynamic non-linear temporal trends in illness severity observed over the course of the study period for all patients as well as among hospitalised patients. Racial/ethnic differences in temporal trends in illness severity were evaluated using likelihood ratio tests between models with and without interaction terms between race/ethnicity and the cubic spline variable representing time. To further evaluate severity of illness at different time points throughout the study period, we also fit models stratified by time period. Racial/ethnic differences in illness severity across the four discrete time periods were evaluated using joint hypothesis testing. All analyses were conducted using R V.3.4.1 (R Foundation for Statistical Computing, Vienna, Austria) and p values <0.05 were considered significant.

### Patient and public involvement

Patients and the public were not involved in the development of this study.

## RESULTS

### Cohort characteristics

We identified a total of 1636 COVID-19-positive patients admitted to the hospital, of whom 51 (3.1%) did not have documented race or ethnicity and 1 did not have a documented date of birth and were thus excluded from analyses. For the final sample, including 1584 patients, the mean age was 61.6±19.8 years, 874 (55.2%) were men, the median household income was estimated at $36 118 (IQR $23 359–$54 207), and the mean SES index was 56.6±6.8

**Figure 1**   Cumulative COVID-19 cases over time by race/ethnicity.

(table 1). Hypertension was the most common comorbidity (47.1%), followed by diabetes mellitus (29.3%) and prior myocardial infarction or heart failure (24.5%). A total of 651 (41.1%) identified as NHW, 262 (16.5%) as NHB, 491 (31.0%) as Hispanic/Latinx, 93 (5.9%) as Asian and 87 (5.5%) as other race/ethnicity. Compared with NHWs, Hispanic/Latinx and NHB patients tended to be younger, have lower estimated median income and higher rates of diabetes mellitus; NHBs also tended to have higher frequency of hypertension, while hypertension was less common among Hispanic/Latinx patients (table 2).

During the study period, 201 (12.7%) patients required ICU admission without need for intubation and 156 (9.8%) required intubation or suffered in-hospital death. The frequency of clinical outcomes, by level of illness severity, is shown by racial/ethnic group in online supplemental table 1. Among patients admitted to the hospital for whom vital sign data from the emergency department were available (n=1551), we examined the first-encounter vital signs. The distribution of first-encounter vital signs overall and by racial/ethnic group is shown in online supplemental table 2. We observed statistically significant differences across racial/ethnic groups in certain

first-encounter vital signs, although for very narrow average ranges of difference: oxygen saturation (difference range <1%), heart rate (<5 beats per minute) and systolic blood pressure (<6 mm Hg).

### Crude temporal variations

The average daily rate of new COVID-19 admissions was 5.7±3.9 cases per day over the study period, with variations seen over time (figure 1). We observed COVID-19 admission rates peaked in periods 1 and 4 (6.1±3.5 and 8.6±6.0 cases per day, respectively) and nadir in periods 2 and 3 (5.9±2.7 and 4.0±2.5 cases per day, respectively) (table 1). The average patient age was highest at the beginning of the pandemic in period 1 (66.9±19.1), lowest in period 3 (58.8±20.2) and increased again in period 4 (61.7±18.6). Overall comorbidity status, as measured by the ECI, was highest in periods 1 and 4 (11.2±12.5 and 11.9±13.7, respectively) and lowest in period 2 (8.9±11.8). Similar trends were observed among NHWs in analyses stratified by race/ethnicity (online supplemental table 3). NHBs did not demonstrate similar reductions in ECI during period 2 and ECI was relatively lower for Hispanic/Latinx patients throughout the study period. Rates of intubation and death steadily decreased over time, while ICU utilisation initially declined from periods 1 to 3 before increasing again during period 4 (table 2). Similar trends were appreciated when outcomes were stratified by race/ethnicity.

### Multivariable-adjusted temporal variations by race and ethnicity

In multivariable analysis, we observed that the risk of developing more severe illness steadily decreased over time (figure 2). When stratified by race/ethnicity, Hispanic/Latinx patients were more likely to experience severe illness compared with NHWs (OR 2.28, 95% CI 1.62 to 3.22). This finding was consistent across time periods, except for time period 3, although a non-significant trend towards more severe disease for Hispanic/Latinx populations was still observed. Similar to analyses of overall

illness severity, NHB patients were more likely to experience more severe illness than NHWs in periods 1 and 4 (2.02, 1.07 to 3.78; and 2.66, 1.08 to 6.48, respectively), without significant differences appreciated during the remainder of the study period (table 3, online supplemental figure 1).

## DISCUSSION

In our high-volume academic medical centre, serving a diverse urban population that has been substantially affected by the pandemic, we found that COVID-19 illness severity steadily decreased over time. However, the temporal improvement in severity of COVID-19 illness among our patients was not seen evenly across racial/ethnic groups. Importantly, among patients hospitalised for COVID-19, Hispanic/Latinx patients were consistently at the highest risk for the most severe forms of COVID-19 illness compared with NHWs, and this disparity not only persisted throughout the course of the pandemic but may be worsening with time. Further, improvements in disparate outcomes for NHBs seen earlier in the pandemic appear to be re-emerging.

Our findings extend from prior reports of minority populations experiencing greater severity of illness and poorer outcomes due to COVID-19. As early as March 2020, emerging studies indicated that NHBs were being hospitalised at 33% higher rates than expected across the USA.[16] Data collected from subsequent single-site[17–21] and regional studies nationally[22 23] and globally[24 25] also confirmed disproportionately worse COVID-19 outcomes being experienced by racial/ethnic minority populations. Our findings confirm that racial/ethnic disparities in COVID-19 outcomes not only exist across a large metropolitan population in Southern California, but that these disparities are persisting over time—even after accounting for variations in underlying pre-existing comorbidities that are known to influence illness susceptibility. In fact, Hispanic/Latinx patients in our sample have greater risk

for more severe forms of COVID-19 illness even while consistently being younger and with fewer comorbid conditions compared with NHWs. Importantly, our data highlight an elevated risk of severe COVID-19 illness in Hispanic/Latinx patients has not only been constant over time but appears to be increasing. For most of the study period, hospitalised Hispanic/Latinx patients were more than twice as likely to require ICU admission, be intubated or die than NHW patients; now, by the end of the study period, Hispanic/Latinx are nearly four times as likely to suffer severe COVID-19 illness. By contrast, initially observed disparities for NHBs disappeared within 2–3 months into the pandemic, but are now re-emerging, with NHBs 2.7 times as likely to suffer severe COVID-19 illness during the most recent time period in our study.

There are several potential explanations for our findings. The overall decline in COVID-19 illness severity, with a reported mortality rate as high as 16.6% in January–April and declining to 9.3% by May–June,[26] has been associated with broadening demographics of the populations at risk, in addition to rapidly advancing therapeutics such as remdesivir, baricitinib and monoclonal antibodies.[27–29] As for other disease states, new therapeutics are often not available to all segments of society simultaneously and thus can exacerbate disparities in healthcare access, utilisation and outcomes.[30–32] Beyond variations in access to therapeutics, racial/ethnic disparities in clinical outcomes can arise from the complex interplay between sociodemographic factors and intrinsic disease risk.[33] For Hispanic/Latinx compared with NHW patients in our sample, the only characteristic that consistently differed was lower SES index (driven in part by lower estimated median household income). Factors related to lower SES may have led to a greater delay in presentation with COVID-19 illness even though we did not observe clinically meaningful racial/ethnic differences in first-encounter vital signs. Unmeasured or otherwise undetected subclinical risk factors may also be driving the persistent disparities

seen in our sample. For example, malnutrition and low levels of vitamin D have each been associated with adverse COVID-19 outcomes, but were unable to be adequately controlled for in this analysis.[34 35] Notably, at least one prior study of racial/ethnic disparities in COVID-19 severity, involving over 2600 patients hospitalised in New York City during the first few months of the pandemic, paradoxically found that NHBs and Hispanic/Latinx patients had less illness severity than NHW patients.[36] In accordance with other studies reporting more affluent and travelled individuals more affected earlier in the pandemic,[37] followed by less affluent and more essential worker individuals increasingly affected later in the pandemic,[33] severity of COVID-19 illness may be determined by relative dose, type, timing and chronicity of SARS-CoV-2 exposure on top of factors specific to race/ethnicity and SES.

Several limitations to our study merit consideration. Our data were derived from a single healthcare system, although high-volume and serving a dense and diverse urban population. The extent to which our findings are generalisable to other populations requires further investigation. Our analyses relied on the AHRQ SES index as a surrogate for patient SES. Importantly, this variable is a marker of SES of the entire community in the census tract in which a patient lives and may not be reflective of an individual patient's own SES. While this is a well-accepted method for controlling for SES, patient-level data (individual patient employment status, income, housing and so on) would allow for improved controlling for SES but were not readily available through medical records for the present study. Finally, race and ethnicity are complex sociocultural entities[38] which often oversimplify the heterogeneity that exists within broadly defined categories. For example, more granular analyses of ethnic disparities can be pursued by examining subgroups of Hispanic/Latinx communities identified using data on ancestry, immigration status and degree of acculturation. Although the racial/ethnic categories in this analysis are widely used to examine group differences across the population, they do not represent the range of experiences, situations and other factors pertinent to the individual members of these various populations.

In summary, our study findings highlight temporal trends in the severity of COVID-19 illness that are particularly relevant to the health of racial/ethnic minorities. Specifically, while severity of illness decreased among the entire population over time, Hispanic/Latinx patients consistently experienced greater illness severity than NHWs throughout the pandemic, despite having similar hospitalisation rates and a lower burden of pre-existing risk factors. Whereas NHBs in our patient population experienced more severe illness when the pandemic first began, their clinical outcomes improved in the middle of the study period, only to re-emerge later on. Further concerning is the finding that this disparity is not only persisting but potentially even worsening over time. Future studies are needed to comprehensively determine the extent to which this Hispanic/Latinx and NHB disparity represents biological differences in susceptibility to severe COVID-19 illness or variations in the social determinants of health, or both.
