Background: Few data are available about the effects of respiratory muscle training with normocapnic hyperpnea (NH) in COPD. The aim is to evaluate the effects of 4 weeks of NH (Spirotiger[®]) on ventilatory pattern, exercise capacity, and quality of life (QoL) in COPD patients.

Methods: Twenty-six COPD patients (three females), ages 49–82 years, were included in this study. Spirometry and maximal inspiratory pressure, St George Respiratory Questionnaire, 6-minute walk test, and symptom-limited endurance exercise test (endurance test to the limit of tolerance [tLim]) at 75%–80% of peak work rate up to a Borg Score of 8–9/10 were performed before and after NH. Patients were equipped with ambulatory inductive plethysmography (LifeShirt[®]) to evaluate ventilatory pattern and thoracoabdominal coordination (phase angle [PhA]) during tLim. After four supervised sessions, subjects trained at home for 4 weeks – 10 minutes twice a day at 50% of maximal voluntary ventilation. The workload was adjusted during the training period to maintain a Borg Score of 5–6/10.

Results: Twenty subjects completed the study. After NH, maximal inspiratory pressure significantly increased (81.5 ± 31.6 vs 91.8 ± 30.6 cmH₂O, $P < 0.01$); exercise endurance time (+150 seconds, $P = 0.04$), 6-minute walk test (+30 meters, $P = 0.03$), and QoL (–8, $P < 0.01$) all increased. During tLim, the ventilatory pattern changed significantly (lower ventilation, lower respiratory rate, higher tidal volume); oxygen desaturation, PhA, and dyspnea Borg Score were lower for the same work intensity ($P < 0.01$, $P = 0.02$, and $P < 0.01$, respectively; one-way ANOVA). The improvement in tidal volume and oxygen saturation after NH were significantly related ($R^2 = 0.65$, $P < 0.01$).

Conclusion: As expected, NH improves inspiratory muscle performance, exercise capacity, and QoL. New results are significant change in ventilatory pattern, which improves oxygen saturation and an improvement in thoracoabdominal coordination (lower PhA). These two facts could explain the reduced dyspnea during the endurance test. All these results together may play a role in improving exercise capacity after NH training.

Keywords: COPD, exercise, inspiratory muscle, pulmonary rehabilitation

Introduction

Dyspnea is the primary symptom that limits exercise in many patients with COPD.^{1,2} In COPD, exercise limitation is clearly multifactorial; one of the main contributors¹ is ventilatory limitation due to increased airway resistance and pulmonary hyperinflation, both increasing the work of breathing.^{3–5} In addition, COPD patients exhibit

Email bernardi.eva@gmail.com

abnormal thoracoabdominal motion during exercise and this is another cause of exercise limitation.^{6–9} In particular, Chien et al⁹ showed that asynchronous thoracoabdominal motion occurred early during exercise in patients with mild COPD, contributing to a decreased 6-minute walk distance. Respiratory muscle weakness can also play a role in dyspnea perception and exercise limitation. Indeed, inspiratory muscle weakness is observed in COPD patients^{10,11} and contributes to dyspnea perception.^{1,12,13}

For this reason, there has been an interest in applying a specific training to the inspiratory muscles in COPD patients. Different forms of respiratory muscle training (RMT) have been used, and from recent meta-analyses^{14,15} it is clear that RMT increases inspiratory muscle performance and functional exercise capacity (ie, 6-minute walk distance, endurance exercise capacity, and maximal oxygen consumption^{14,15}), and decreases dyspnea, but the clinical importance of these improvements remains unclear. Most studies investigated the effects of RMT with resistive or threshold loading,¹⁴ while a few studies evaluated^{16–18} the effects of RMT with normocapnic hyperpnea (NH) even though Koppers et al¹⁶ reported that NH could be the most appropriate technique for improving respiratory muscle endurance capacity, which is required during endurance exercises.

None of these studies^{16–18} investigated the effects of NH on thoracoabdominal coordination and oxygen saturation (SpO₂) during exercise in COPD patients, whereas only one study¹⁶ investigated the effects of NH on the ventilatory pattern, showing lower minute ventilation and respiratory rate and larger tidal volume during exercise.

The aim of this study was to evaluate the effects of 4 weeks of NH (using the Spirotiger[®] device) on thoracoabdominal coordination, SpO₂, ventilatory pattern, exercise capacity, and quality of life (QoL) in COPD patients.

Methods

Subjects were consecutively recruited from the outpatient clinic of the Department of Respiratory Disease, Ferrara University Hospital, Italy.

Inclusion criteria were as follows: 1) COPD as defined according to international guidelines;¹⁹ 2) forced expiratory volume in 1 second (FEV₁) between 30% and 80% predicted,²⁰ after bronchodilatation; and 3) stable clinical condition for at least 6 weeks. Exclusion criteria were as follows: 1) cardiac comorbidity (ie, recent myocardial infarction, myocardial ischemia, and cardiac arrhythmia); 2) inability to use the device; and 3) inclusion in any pulmonary rehabilitation program.

The Ethics Committee of the University of Ferrara approved the study (protocol number 090591). Informed consent was obtained from each subject.

Study design

On the first day of the study, patients performed a respiratory function test (forced flow–volume curve) and their inspiratory muscle strength (maximal inspiratory pressure [MIP]) was measured. After 30 minutes of rest, a 6-minute walk test (6MWT) was performed.²¹ The St George Respiratory Questionnaire (SGRQ) for measuring health-related QoL was completed.²²

On the second day, an incremental walking test was performed, followed, after 30 minutes of rest, by an endurance test to the limit of tolerance (tLim) (ie, until subjects were unable to continue due to symptoms). Daily physical activity was monitored using the SenseWear Armband[®] (BodyMedia, Pittsburgh, PA, USA) validated for estimating energy expenditure in COPD patients.^{23,24}

After 4 weeks of respiratory muscle endurance training (NH), the subjects repeated all the tests in a standardized manner and sequence.

The testing and the training procedure are detailed in the sections Exercise testing and Respiratory muscle endurance training.

Respiratory function

The forced flow–volume curve was performed (JAEGER[®] MasterScreen Body; San Diego, CA, USA) to measure forced vital capacity and FEV₁. In accordance with the guidelines of the American Thoracic Society/European Respiratory Society,²⁵ subjects repeated the maneuver at least three times and the two largest values of forced vital capacity and FEV₁ had to be within 0.15 L of each other. Reference normal values were taken from the European Community for Steel and Coal.²⁰

After respiratory function, MIP was measured; starting from residual volume, the subject was asked to inspire as deeply as possible, maintaining the maximal pressure for at least 1.5 seconds. The pressure was measured with a manometer (CARDINAL Health microRPM[®]; San Diego, CA, USA). Subjects repeated the maneuver a minimum of five times and reproducibility had to be within 5%–10% in accordance with the guidelines.²⁶ The highest value was considered for comparison before and after training.

Exercise testing

The 6MWT was performed in a corridor 24 m long. The subjects were instructed to cover as much distance as possible

in 6 minutes and standardized verbal encouragement was given.²¹ The maximum distance walked was recorded.

The maximal incremental exercise test was performed on a treadmill (Runner Galaxy MTC, Cavezzo, Italy). During the test, the work rate was increased every 10 meters by 0.2 km/h.²⁷ Arterial blood pressure was measured every minute. Heart rate and SpO₂ were continuously monitored. At the end of the test, maximal working capacity (Speed_{max}) was recorded.

A constant-load endurance exercise test was performed on a treadmill at a work rate of 80%–85% of the individual's Speed_{max} and continued to the tLim.²⁸ Subjects were not encouraged during the test. Perception of dyspnea and muscular fatigue were measured using the Borg Scale²⁹ at regular intervals. The tLim was terminated when the subjects indicated they were unable to continue due to intolerable dyspnea and/or muscular fatigue (Borg Score 8–9/10), or were unable to keep up with the speed of the treadmill; the duration of the test was recorded as walking endurance time.

During tLim, patients were equipped with ambulatory inductive plethysmography (LifeShirt® System, San Diego, CA, USA).³⁰ The LifeShirt® features rib cage and abdominal inductance bands embedded within an elasticized vest, connected to a battery-operated handheld computer. The handheld computer continuously records data. Before each test, a calibration of the system was performed. After the testing session, the data were downloaded and analyzed with a dedicated software (Vivologic 3.0, Vivonoetics, San Diego, CA, USA) for calculating respiratory variables: ventilation, tidal volume, and respiratory rate. The phase angle (PhA) was obtained as a measure of asynchrony between rib cage and abdominal movements (thoracoabdominal asynchrony). A pulse oximeter and an electrocardiograph were integrated into the LifeShirt system.

Respiratory muscle endurance training

The training protocol lasted 4 weeks and was performed by means of Spirotiger® (MVM, Linate, MI, Italy), which consists of a handheld unit with a pouch and a base station. A two-way piston valve connected to a rebreathing bag permits a constant isocapnic end-tidal CO₂ fraction³¹ to be maintained.

Before starting the protocol, subjects underwent four supervised training sessions to learn the technique and to define the target training ventilation. In accordance with previous studies,^{16–18} the size of the bag was adjusted to 50%–60% of the subject's vital capacity and the breathing frequency chosen was such that ventilation corresponded to 50%–60% of maximal voluntary ventilation (calculated as 35 times FEV₁). The tidal volume was adjusted by changing

the size of the bag and breathing frequency was changed accordingly to maintain target training ventilation (ie 50%–60% of maximal voluntary ventilation). The subjects trained 20 minutes daily (1 minute of exercise and 1 minute of rest, ten times, twice a day), 7 days a week, for 5 weeks. While performing NH, the patients wore a nose clip to ensure breathing occurred exclusively through the training device.

During the training period, a diary documented the compliance with home-based training: number, duration of the sessions, and rating of perceived respiratory exertion (Borg Score) were reported.

Statistical analysis

Data are reported as mean ± standard deviation. The Student's *t*-test was used to compare baseline characteristics and training changes. The one-way ANOVA test with analysis of the covariate was used to evaluate the effects of training on ventilation, ventilatory pattern, and PhA; the *P*-values were adjusted according to the Bonferroni correction. The parametric Pearson correlation coefficient was used to describe the relationships between variables. Statistical significance was accepted at *P*<0.05. All the analyses were performed using GraphPad Prism 40.

Results

Twenty-six patients were included in the study. Baseline characteristics of the subjects are shown in Table 1. The mean age of the study population was 69±8 years. According to Armband® data, the physical activity status of the subjects was between low and moderate (Table 1). Medication was not changed during the study period.

Table 1 Baseline characteristics (26 subjects)

| Variables | T0 |
|--------------------------------------|-----------|
| Age (years) | 69±8 |
| Weight (kg) | 83.5±13.2 |
| Body mass index (kg/m ²) | 29.4±4.8 |
| FEV ₁ (L) | 1.49±0.47 |
| FEV ₁ (% pred) | 56±16 |
| FVC (L) | 2.63±0.84 |
| FVC (% pred) | 75±21 |
| FEV ₁ /FVC (%) | 57±13 |
| MIP (cmH ₂ O) | 81.5±31.6 |
| MIP (% pred) | 81±33 |
| SGRQ (total) | 29.6±16.8 |
| Daily physical activity (METs) | 1.4±0.2 |

Note: Data are expressed as mean ± SD.

Abbreviations: FEV₁, forced expiratory volume in 1 second; FEV₁ (% pred), % of predicted value of forced expiratory volume in 1 second; FVC, forced vital capacity; MIP, maximal inspiratory pressure; SGRQ, St George Respiratory Questionnaire; T0, baseline; SD, standard deviation; MET, metabolic equivalent of task.

Twenty patients completed the study. Six patients did not complete the study: two because of poor tolerance to the device, three because of poor compliance, and one because of excessive fatigue.

Intriguingly, at baseline (T0), a positive correlation is found between MIP and FEV₁ as a percentage of predicted values (Figure 1A) and between MIP and the 6MWT (Figure 1B); an inverse correlation is shown between MIP and the total SGRQ score (Figure 1C).

NH training

Analysis of the diaries showed that all patients trained 20 minutes daily, every day at a workload corresponding to 51% of maximal voluntary ventilation with a mean Borg Score of 6/10.

Inspiratory muscle performance

Table 2 shows the effects of 4 weeks of home-based NH on respiratory function and muscle strength. After training (T1), MIP significantly increased (+10.3 cmH₂O; Student's *t*-test, *P*=0.0001). A strong correlation was found between the value at T0 and at T1 (*R*²=0.90, *P*<0.00001). The probability plot distribution confirms normal distribution of the data.

Exercise performance and ventilatory pattern

The effects of NH on exercise performance are shown in Table 2.

Regarding the 6MWT, the distance covered increased by 30 m (Student's *t*-test, *P*=0.03).

The duration of tLim significantly increased by 2 minutes and 30 seconds (Student's *t*-test, *P*=0.04); during the test, average speed was 4.8±0.9 km/h, corresponding to 79% of Speed_{max} (6.1±1.2 km/h).

Regarding ventilatory data, a significant increase in tidal volume at rest was shown (T0: 0.29±0.74 mL and T1: 0.32±0.81 mL; Student's *t*-test, *P*=0.02). During tLim, after the training, significantly lower ventilation and respiratory rate were found (one-way ANOVA, *P*<0.05; Figure 2A–C for ventilation, respiratory rate, and tidal volume, respectively). Furthermore, a lower increase in PhA was found during exercise (one-way ANOVA, *P*=0.02; Figure 3).

Regarding SpO₂, an improvement was found at rest (Student's *t*-test, *P*=0.02; Table 2). The SpO₂ monitoring during tLim showed significantly higher values (one-way ANOVA, *P*<0.01; Figure 4).

Figure 1 Correlation between MIP and FEV₁ (A), 6MWT (B), and SGRQ (C) before the training.

Abbreviations: FEV₁, forced expiratory volume in 1 second; 6MWT, 6-minute walk test; SGRQ, St George Respiratory Questionnaire; MIP, maximal inspiratory pressure.

Table 2 Pretraining and posttraining values (20 subjects)

| Variables | T0 | T1 |
|-----------------------------------|-------------|-------------|
| Respiratory function | | |
| FEV ₁ (L) | 1.54±0.44 | 1.56±0.39 |
| FVC (L) | 2.57±0.84 | 2.82±0.77 |
| Respiratory muscle pressure | | |
| MIP (cmH ₂ O) | 81.5±31.6 | 91.8±30.6* |
| Exercise performance | | |
| 6MWT (meters) | 423±71 | 453±73* |
| tLim | | |
| Time (seconds) | 347±235 | 497±410* |
| Heart rate rest (bpm) | 80±13 | 77±14 |
| Heart rate max (bpm) | 123±19 | 123±14 |
| SpO ₂ rest (%) | 94±2 | 95±2* |
| SpO ₂ min (%) | 90±4 | 91±2 |
| Dyspnea Borg Score (/10) | 8±1 | 8±1 |
| Muscular fatigue Borg Score (/10) | 7±1 | 7±2 |
| SGRQ (total) | 29±17 | 21±12* |
| Daily physical activity (METs) | 1.5±0.2 | 1.5±0.2 |
| Number of steps | 7,210±2,388 | 7,720±4,199 |

Notes: Data are expressed as mean ± SD. *Student's *t*-test, $P < 0.05$.

Abbreviations: FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; MIP, maximal inspiratory pressure; 6MWT, 6-minute walk test; tLim, endurance test to the limit of tolerance; SpO₂, oxygen saturation; SGRQ, St George Respiratory Questionnaire; T0, baseline; T1, after 4 weeks of respiratory muscle training; SD, standard deviation; bpm, beats per minute; MET, metabolic equivalent of task; min, minimum.

After training, a correlation was found during tLim between the changes in tidal volume and SpO₂ (Figure 5).

All these findings were associated with lower dyspnea and muscular fatigue Borg Score (one-way ANOVA, $P < 0.01$; Figure 6A and B, respectively).

Discussion

The aim of this study was to evaluate the effects of 4 weeks of inspiratory muscle training with NH on ventilatory pattern, exercise capacity, and QoL in COPD patients. The main results are the changes in ventilatory pattern and the improved thoracoabdominal coordination during exercise after training.

Regarding the ventilatory pattern, after training at the same work intensity, we found lower ventilation, a decrease in respiratory rate, and an increase in tidal volume. The slower and deeper ventilation allows improved alveolar ventilation, which in turn has an effect on gas exchange. The subjects exhibit improved oxygenation, which is related to the increase in tidal volume. Improved oxygenation is already evident at rest when the ventilatory pattern is characterized by a higher tidal volume at the same ventilation. Several studies^{32–34} have already shown that deeper and slower breathing (so-called yoga breathing) improves SpO₂ in both healthy subjects exposed to high altitude³² and subjects suffering from chronic diseases such as heart failure³³ and COPD.³⁴

To our knowledge, only Koppers¹⁶ has described the ventilatory pattern changes after NH, but only during exercise. In his study,¹⁶ he also highlights that deeper and slower ventilation reduces the work of breathing, delaying respiratory muscle fatigue, and dyspnea perception. Moreover, improved thoracoabdominal coordination plays a key role in dyspnea perception, even though few data are available in literature.

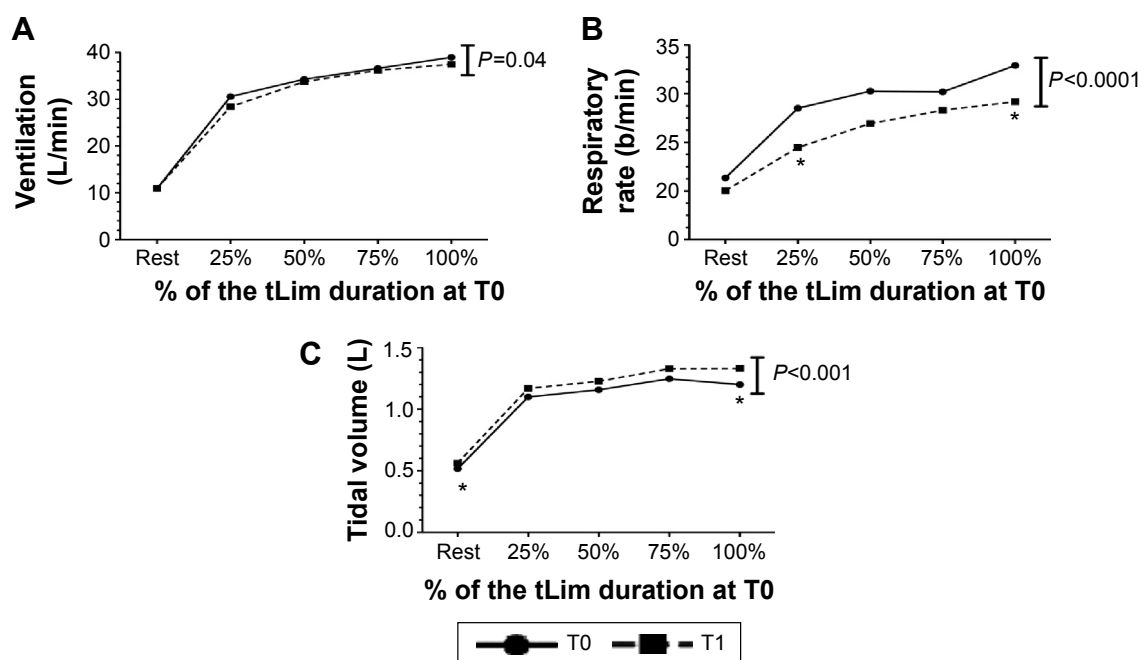

Figure 2 The ventilation (A), respiratory rate (B), and tidal volume trend (C) during tLim before T0 and after T1 training.

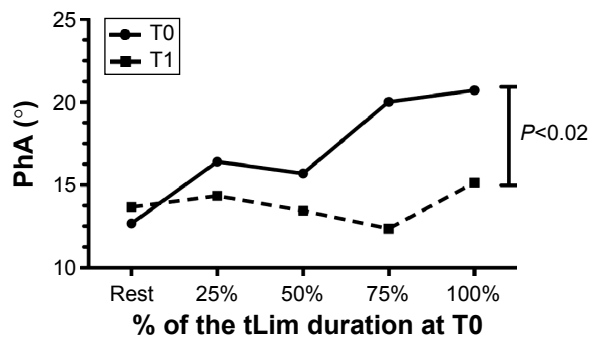

Figure 3 The PhA trend during tLim before and after training.

Notes: ANOVA test between T0 and T1. Mean value at rest, at 25%, 50%, 75%, and 100% of the tLim duration at T0.

Abbreviations: PhA, phase angle; tLim, endurance test to the limit of tolerance; T0, baseline; T1, after 4 weeks of respiratory muscle training.

Indeed, only two studies^{9,35} have investigated this asynchrony in COPD subjects. In particular, Chien⁹ has shown that thoracoabdominal asynchrony reduces exercise capacity in moderate and severe COPD. The mechanism, however, remains unclear.^{36,37} Our results are in line with this result; in fact, in our study, patients with moderate and severe COPD show an increased exercise capacity together with better thoracoabdominal coordination. Both the change in ventilatory pattern and the improved thoracoabdominal coordination can explain the reduction in dyspnea perception.

Besides the innovative results related to ventilation, we also found a significant increase in inspiratory muscle strength after NH. This is a quite controversial point. In fact, it is clear from meta-analyses^{14,15} that NH increases inspiratory muscle endurance and only one study¹⁸ showed that it improved respiratory muscle strength. However, the

Figure 4 The SpO₂ trend during tLim before and after training.

Figure 5 Correlation between the changes in tidal volume and SpO₂, before and after training, during tLim.

Abbreviations: SpO₂, oxygen saturation; tLim, endurance test to the limit of tolerance.

increase in respiratory muscle strength, and not just endurance, is clinically relevant to COPD patients.^{38,39} In fact, Terzano et al³⁸ and Tudorache et al³⁹ have demonstrated that airway obstruction is closely associated with lower respiratory muscle pressures. In our study, we also found, at baseline, a correlation between MIP and the severity of bronchial obstruction. Furthermore, Tudorache et al³⁹ found a correlation between MIP and the 6MWT distance, as in our study. However, to the best of our knowledge, there is no study in literature demonstrating a significant inverse correlation between MIP and QoL.

Regarding exercise capacity, the positive effects of NH in COPD^{16–18} are already known. In this study, we have found a higher duration of the endurance test (+43%) and an increase in walking distance during the 6MWT (+30 m), which are the minimal important difference.^{28,40,41}

Another interesting point is the evidence that the level of physical activity of the subjects did not change during the study period. The use of the multi-sensor Armband[®] allowed us to verify that the energy expenditure and the number of daily steps did not change significantly after NH. Therefore, no significant physical activity changes could have influenced our results.⁴²

This study has some limitations. The main limitation is the absence of a sham group. So far, there is no instrument available that allows NH without any workload, which should be the gold standard for control group training. Among all papers discussing NH, only three^{17,18,43} studied a control group training with an incentive spirometer with minimal resistance and a low respiratory rate; however, this device does not completely satisfy our purposes.

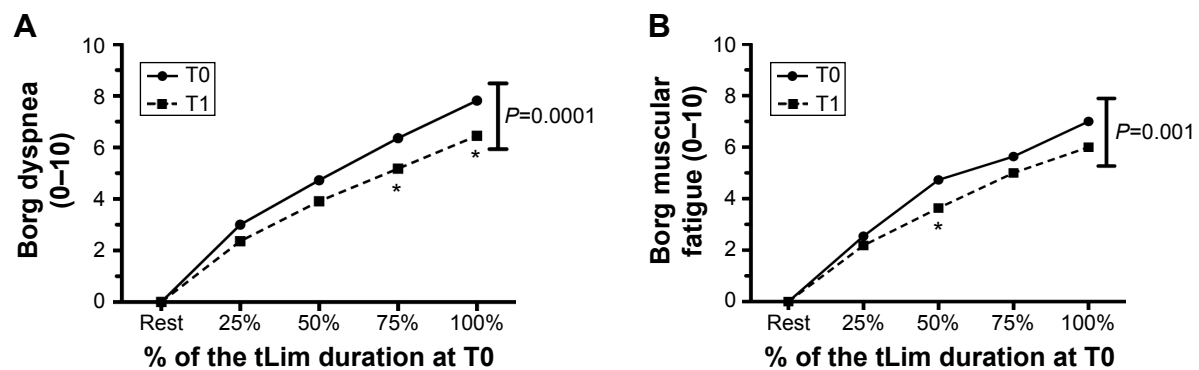

Figure 6 The Borg dyspnea (A) and muscular fatigue (B) trend during tLim before and after training.

Notes: ANOVA test between T0 and T1. Mean value at rest, at 25%, 50%, 75%, and 100% of the tLim duration at T0. * $P < 0.05$ between T0 and T1.

Abbreviations: tLim, endurance test to the limit of tolerance; T0, baseline; T1, after 4 weeks of respiratory muscle training; ANOVA, analysis of variance.

Another limitation is the high number of dropouts (23%). A careful analysis of the characteristics of these subjects could have helped us to better identify the subjects that could benefit from this training. However, we did not find any significant differences between the two groups as regards age, respiratory function, exercise capacity, anthropometric characteristics, and QoL. All subjects but one dropped out because of poor compliance and poor adaptation to the device. Therefore, it seems that motivation is the main factor for completing the training.

Conclusion

NH is an effective treatment for COPD to improve respiratory muscle strength, ventilatory pattern, and thoracoabdominal coordination, which have a positive effect on SpO_2 . As a consequence, dyspnea perception decreases, exercise capacity increases, and QoL improves. These preliminary results seem to show that NH can be used as a nonpharmacological therapy to complement exercise, or as an alternative aid for COPD patients to improve exercise capacity and QoL.

International Journal of COPD

Publish your work in this journal

The International Journal of COPD is an international, peer-reviewed journal of therapeutics and pharmacology focusing on concise rapid reporting of clinical studies and reviews in COPD. Special focus is given to the pathophysiological processes underlying the disease, intervention programs, patient focused education, and self management protocols.

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-chronic-obstructive-pulmonary-disease-journal>

Dovepress

This journal is indexed on PubMed Central, MedLine and CAS. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
