Blastic Plasmacytoid Dendritic Cell Neoplasm: Analysis of Clinicopathological Feature and Treatment Outcome of Seven Cases

Jun-Hwan Kim, Hae-Young Park, Jong-Hee Lee, Dong-Youn Lee, Joo-Heung Lee, Jun-Mo Yang

Department of Dermatology, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea

Background: Blastic plasmacytoid dendritic cell neoplasm (BPDCN), which is derived from the precursor of plasmacytoid dendritic cells, is a rare and highly aggressive hematologic malignancy. It has only recently been recognized as a distinct entity. BPDCN characteristically has a predilection for cutaneous involvement. **Objective:** The aim of this study was to describe the clinical and pathological features of BPDCN, and to review the treatment courses to analyze the prognosis and the optimal therapeutic approach. **Methods:** We retrospectively reviewed seven BPDCN cases registered in the Samsung Medical Center database between January 2010 and December 2014. **Results:** The median age of the patients was 52 years (range, 18～79 years), and six patients were male. The clinical staging was as follows: skin (n=5), lymph node (n=6), bone marrow (n=4), and peripheral blood (n=2). The skin manifestations were bruise-like tumefaction (n=4), erythematous nodule (n=4), or multiple erythematous papules (n=1). The pathological evaluation revealed dense diffuse or nodular infiltration of neoplastic cells, which were positive for CD4, CD56, and CD123 in the immunohistochemical analysis. Six patients received multiagent chemotherapy as the first-line treatment, alone (n=4), or followed by stem cell transplantation (SCT, n=1) or concurrent radiotherapy (n=1). The median progression-free survival after the first-line treatment was 6 months (range, 2～12 months). **Conclusion:** Three different skin manifestations were observed, with pathological features analogous to each other. All patients who received chemotherapy without SCT achieved partial or complete response but experienced relapse. Furthermore, they showed various clinical courses irrelevant to the cutaneous involvement. **(Ann Dermatol 27(6) 727～737, 2015)**

INTRODUCTION

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) is a very rare hematopoietic precursor cell malignancy characterized by a striking predilection for cutaneous involvement[1]. BPDCN was first described in 1994 as a CD4+ lymphoma with a high expression of CD56[2]. BPDCN was formerly called "blastic natural killer (NK) cell lymphoma" or "agranular CD4+ NK cell leukemia"[3,4]. In the past, the NK cell was thought to be the cell of origin, owing to the expression of CD56. However, it was confirmed in 2005 that BPDCN is derived from the precursor of the plasmacytoid dendritic cell (pDC); since then, the World Health Organization (WHO)-European Organization for Research and Treatment of Cancer has replaced the term "blastic NK cell lymphoma" with "agranular CD4+/CD56+ hematodermic neoplasm"[5]. Currently, this neoplasm was renamed as BPDCN, and categorized under "acute myeloid leukemia (AML) and related precursor neoplasms" in the 2008 WHO Classification of Tumors of Haematopoietic and Lymphoid Tissues[6].

*Developed at 4 months after diagnosis; †developed at 12 months after diagnosis.

Currently, there are no formal studies on the incidence of BPDCN in the general population[7]. A few available data indicate that its overall incidence is extremely low, accounting for 0.44% of all hematologic malignancies[8] and 0.7% of cutaneous lymphomas[9]. BPDCN generally occurs in the elderly, with the mean age of affected patients ranging from 60 to 70 years[4,10-12]. It more often affects men than women[7,10-12].

Most BPDCN cases involved the skin, and they present as solitary or multiple, bruise-like or erythematous papules/plaques or tumors[4]. However, it is not unusual that BPDCN is accompanied by extracutaneous involvement, including lymph node (LN), bone marrow (BM), and peripheral blood (PB) involvement. In addition, BPDCN is characterized by a highly aggressive behavior with a poor prognosis, and the potential to eventually progress to AML[1,7].

Since the first report of this entity, most of the reported cases have been in Western populations[7,10,13,14]; however, there was a comparatively small number of studies in Asians. Recently, 24 cases were reported in a Japanese nationwide study[15], and seven cases in a single-center study in Korea[16]. Here, we report seven cases of BPDCN with skin manifestations at a single institution in Korea, and describe the clinical and pathological features, as well as the treatment outcomes.

MATERIALS AND METHODS

A retrospective analysis was conducted among patients with BPDCN, searched on the database of Samsung Medical Center by using the term "blastic plasmacytoid dendritic cell neoplasm," in the period between January 2010 and

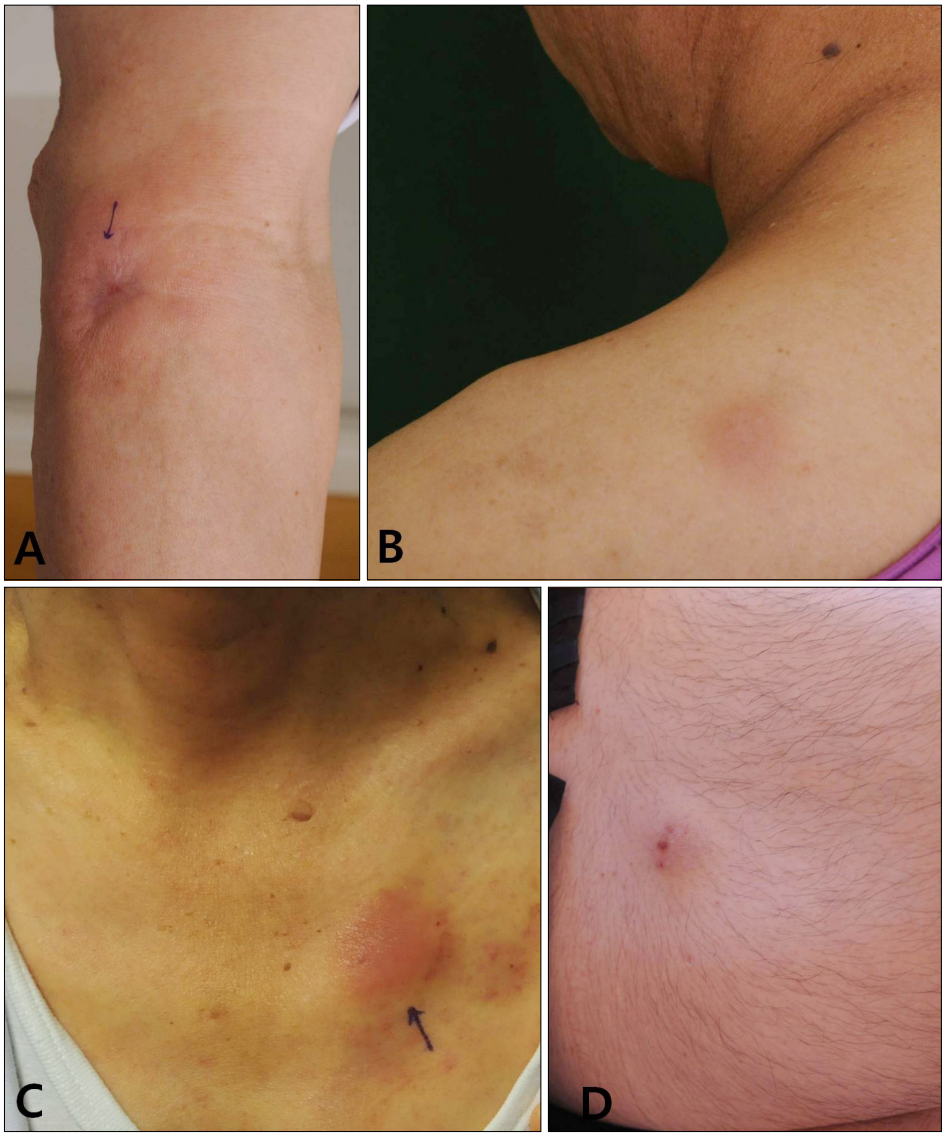

Fig. 1. Clinical presentation. Erythematous nodules on the (A) right elbow, (B) back, (C) chest, and (D) right thigh in patients 1, 2, 3, and 4, respectively.

Fig. 2. Clinical presentation. Bruise-like tumefactions on the (A) upper back, (B) back, (C, D) right cheek, left upper arm, and (E) right shin in patients 1, 4, 5, and 7, respectively.

December 2014. The clinical data collected included sex, age at diagnosis, clinical pictures, complete blood count, blood sample microscopy, evaluations of the BM and LN, cytogenetic data, radiological studies (i.e., computed tomography and positron emission tomography), and pathologic findings of the skin lesion. In addition, treatment information concerning the first-line therapy, treatment response, relapse, and overall survival (OS) was collected.

The WHO 2008 classification system[6] was used for the diagnosis of BPDCN based on clinical, pathological, and immunophenotypical features. Pathological analysis was performed on skin, LN, and BM biopsy specimens. Immunophenotyping was performed by means of immunohistochemical staining. Formalin-fixed, paraffin-embedded tissue blocks were used for the immunohistochemical staining with the following agents: CD3, CD4, CD20, CD56, CD123, myeloperoxidase (MPO), and terminal deoxynucleotidyl transferase (TdT). The pathological diagnosis was made by a specialist at the department of pathology.

7	Admixture of diffuse (upper dermis) and nodular (lower dermis) neoplastic infiltration, extravasated RBCs in the papillary dermis	−	+	−	+	+	−	N	−	Ki-57+, CD8−, ALK−, CD30−	N

N: not tested, RBC: red blood cell, MPO: myeloperoxidase, TdT: terminal deoxynucleotidyl transferase, EBV ISH: Epstein-Barr virus *in situ* hybridization, CK(AE1/AE3): cytokeratin AE1/AE3, ALK: anaplastic lymphoma kinase, PAX5: paired-box 5, *TCRγ*: T-cell receptor γ, *IgH*: Immunoglobulin H.

ized in Table 1. The median age of the patients was 52 years (range, 18～79 years), and six patients were male. At the initial presentation, five patients had skin manifestations. The remaining two patients had no skin lesions (patients 2 and 6) at baseline; however, they showed skin lesions after 4 and 12 months, respectively. Most of the skin lesions appeared as an erythematous nodule (Fig. 1), and/or brownish to bluish infiltrated bruise-like patch/plaque or tumor (Fig. 2). On the other hand, only one patient (patient 6) presented multiple erythematous firm papules (Fig. 3).

Complete staging investigations were applied to all of the patients. LN and BM involvements of BPDCN were found in six and four patients, respectively. PB involvement was found in two patients. Especially, patient 3 showed fever, general weakness, lymphadenopathy, hepatosplenomegaly, leukocytosis, and anemia. Furthermore, his BM evaluation revealed blast cells (up to 70%). These findings were consistent with features of acute leukemia. Conventional cytogenetic studies were performed in all patients. Three patients showed chromosomal abnormalities, including translocation, deletion, derivative chromosomes, and gain or loss of chromosomes in patients 3, 4, and 5, whereas the remaining four patients showed a normal karyotype.

Pathologic findings

For pathological analysis and immunophenotyping, all patients underwent skin biopsies. The results of the skin biopsies are detailed in Table 2. As mentioned above, two patients (patients 2 and 6) had no skin lesion at the initial presentation. However, they showed skin involvement during the follow-up period, and underwent skin biopsies for the evaluation of disease progression. All of the biopsies from different patients, anatomic sites, and time points demonstrated similar histopathological features: diffuse or nodular dense neoplastic infiltration in the dermis, occasionally extending into the subcutaneous tissue, but sparing the epidermis with a Grenz zone (Fig. 4A～C). Some specimens (from patients 6 and 7) showed conspicuous extravasated red blood cells (RBCs) (Fig. 4D). Most of the specimens showed adnexal sparing (Fig. 4E); however, only one specimen (from patient 6) showed infiltrating tumor cells distributed along the adnexa (Fig. 4F). Notably, one specimen (from patient 5) revealed remarkable fibrotic

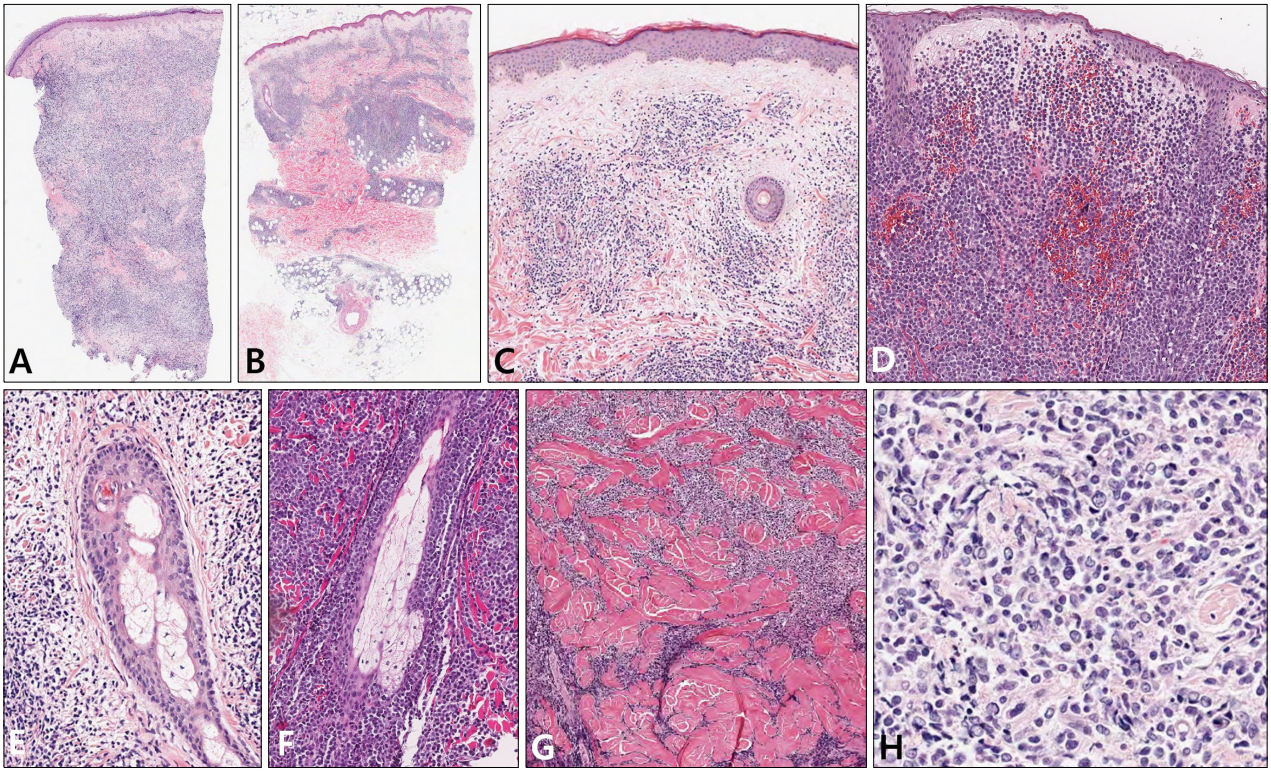

Fig. 4. Pathologic findings of the skin lesion (H&E). (A) Diffuse and (B) nodular infiltration of tumor cells (patients 1 and 2, respectively; ×10). (C) Sparing of the epidermis with a Grenz zone (patient 2; ×40). (D) Extravasation of red blood cells in the tumor cell infiltrate (patient 6; ×40). (E) Sparing of the adnexa (patient 2; ×100). (F) Distribution of the tumor cells along the adnexa (patient 6; ×100). (G) Hypertrophic collagens surrounded by tumor cells (patient 7; ×100). (H) Medium-sized tumor cells containing vesicular nucleus with irregular contour, fine chromatin, and indistinct nucleoli (patient 1; ×200).

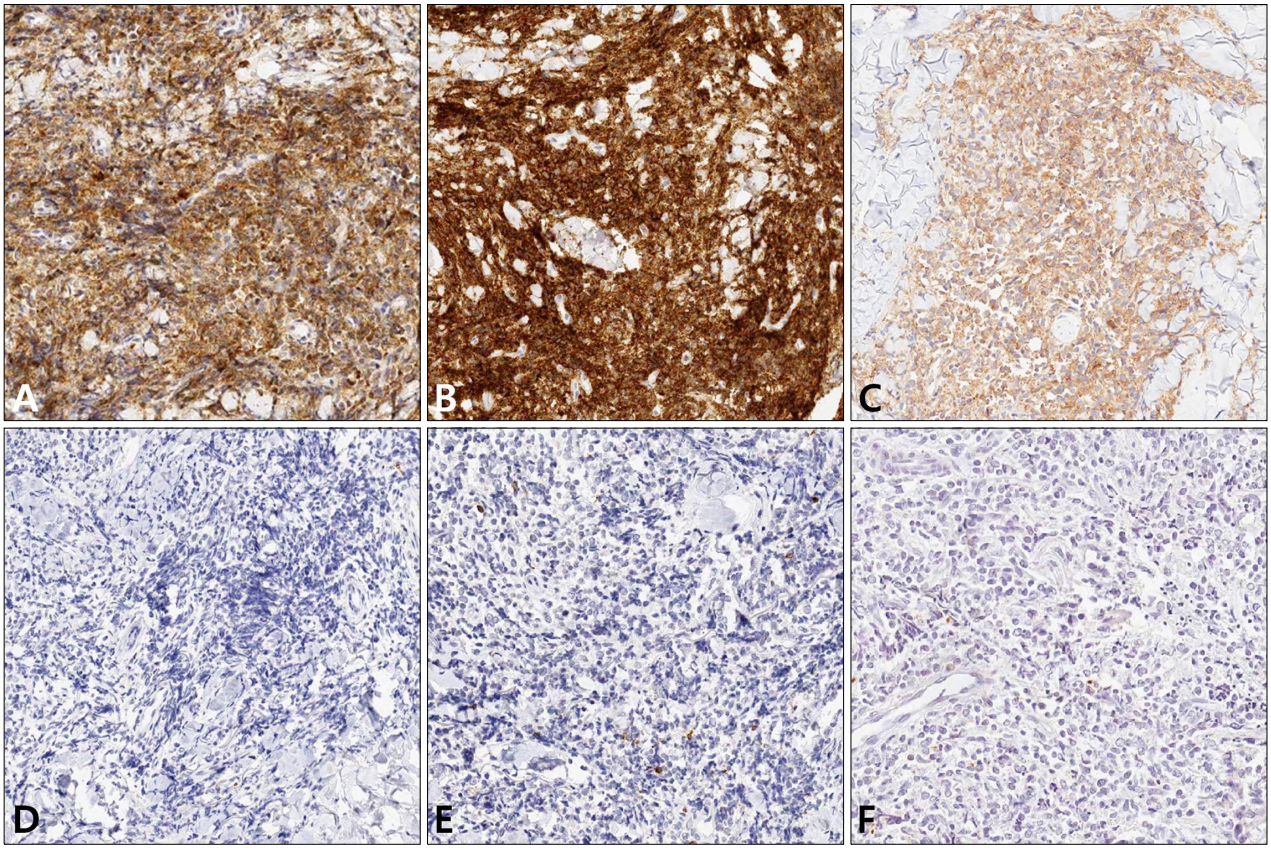

Fig. 5. Immunohistochemical staining revealed positivity for (A) CD4 (×100), (B) CD56 (×100), and (C) CD123 (×100), but negative reactions to (D) CD3 (×100), (E) CD20 (×100), and (F) myeloperoxidase (×100) in patient 1.

changes in the dermis surrounded by tumor cells (Fig. 4G). At high magnification, there were monotonous populations of medium-sized cells containing a vesicular nucleus with irregular contour, fine chromatin, and indistinct nucleoli (Fig. 4H). Occasionally, they showed mitotic figures. The immunophenotyping revealed that the neoplastic cells were positive for CD4 (Fig. 5A), CD56 (Fig. 5B), and CD123 (Fig. 5C), but negative for CD3 (Fig. 5D), CD20 (Fig. 5E), and MPO (Fig. 5F). TdT staining, performed in three patients, was positive in patients 2 and 3 but negative in patient 1.

Treatment and outcomes

The treatment and outcomes of the seven patients are detailed in Table 3. Six patients received multiagent chemotherapy (CTx) as the first-line treatment. The CTx regimens are detailed in Table 3. After the first-line treatment, complete remission (CR) was achieved in four patients (patients 1, 2, 5, and 7); however, all of them showed relapse after 3～12 months. Most (patients 1, 2, 4, 5, and 7) of these patients showed cutaneous lesion as a sign of recurrence. Two (patients 1 and 2) of these patients received salvage CTx or autologous peripheral blood stem cell transplantation (PBSCT); nevertheless, they died because of disease progression and complications. Another one patient (patient 7) showed relapse only in the skin; however, the skin lesion disappeared after skin biopsy. This patient then received only close follow-up, and there has been no disease progression thus far. Patient 5 received palliative radiotherapy (RTx) with CTx, and is being followed to date. Patient 4, who received allogeneic PBSCT after partial remission, showed graft versus host disease (GVHD). Despite the GVHD, this patient maintained a stable disease state for 8 months. However, he had relapse and received salvage CTx. Patient 6 received consolidation RTx on the primary lesion (breast mass) and showed good response. However, after 2 months of RTx, the breast mass grew in size and was confirmed as recurrence on biopsy. Since then, she has received multiagent CTx; however, she showed involvement of the central nervous system and skin. Finally, she achieved a stable disease state and is being followed to date. PBSCT was considered as the primary therapy for her treatment. On the other hand, patient 3 refused any curative treatment at

Table 3. Treatment outcomes

Patient No.	First-line therapy	Response to the first-line therapy	Remarkable features at relapse	PFS (mo)	Salvage treatment	OS (mo), cause of death
1	Hyper-CVAD	CR	Leukemic changes, cutaneous relapse	12	VPDL	25 dead,infection (bacterial meningitis, pneumonia)
2	Hyper-CVAD	CR	*De novo* cutaneous lesions	4	ESHAOX, auto-PBSCT	17 dead, infection (fungal pneumonia, candidiasis)
3	Supportive care	NA	NA	NA	NA	6 dead, unknown*
4	Hyper-CVAD, allo-PBSCT	PR	Cutaneous relapse	8	GDP	17 alive
5	VIDL	CR	Cutaneous relapse	3	RTx, GDP	5 alive

7	VPDL	CR	Cutaneous relapse	8	None	13 alive

PFS: progression-free survival, OS: overall survival, Hyper-CVAD: combination of course A (cyclophosphamide, vincristine, doxorubicin, and dexamethasone) and course B (methotrexate and cytarabine) in an alternating fashion, auto/allo-PBSCT: autologous/allogeneic peripheral blood stem cell transplantation, VIDL: etoposide, ifosfamide, dexamethasone, L-asparaginase, RTx: radiotherapy, VPDL: vincristine, prednisolone, daunorubicin, L-asparaginase, CR: complete remission, PR: partial remission, NA: not available, ESHAOX: etoposide, methylprednisolone, cytarabine, oxaliplatin, GDP: gemcitabine, dexamethasone, cisplatin, SMILE: dexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide, DHAP: dexamethasone, high-dose cytarabine, cisplatin.
*This patient was lost to follow-up, but found to be dead from a National Health Insurance of Korea database.

that time of diagnosis, and received only supportive care. He died after 6 months. The median progression-free survival (PFS) of the patients was 6 months (range, 2～12 months), and the OS was 17 months (range, 5～25 months). In contrast to those without skin lesion at diagnosis, patients with cutaneous involvement at the initial presentation had relatively long PFS. The median PFS was 8 months for those with skin involvement, and 3 months for those without skin involvement. However, the median OS was 15 and 18.5 months, respectively.

DISCUSSION

In this analysis, we describe the clinical and pathological features, and treatment and outcomes of seven cases of BPDCN in the Korean population. Clinically, their presentations were similar to those in previous reports. First, a male predominance was observed. Although a few studies did not show an increased prevalence in males[14,16], it is a universal finding that BPDCN affects male patients more, and the male-to-female ratio ranged from 2 to 7.25[10-13]. Secondly, although the mean age of our patients was slightly younger than in previous reports[7,10,13], they were middle-aged or elderly, except for one teenage patient. Third, all of our patients showed cutaneous involvement. Although two patients had no skin involvement at the initial diagnosis, they presented cutaneous lesions during the follow-up period. As a rule, BPDCN has a predilection to the skin; about 70%～85% of BPDCN cases had shown skin manifestations as the initial presentation in previous studies[7,14,17]. Finally, our study revealed that the most common skin manifestation was bruise-like tumefaction or an erythematous nodule. These findings are similar to those of other previous studies[10,13]. Notably, patient 6 in the present report had a breast mass as the initial presentation. It was similar to the case that Borchiellini et al.[18] reported for the first time in 2013.

Pathological evaluation and immunophenotyping play an important role in the diagnosis of BPDCN[1,4,18]. In cutaneous lesions, BPDCN characteristically infiltrates the dermis but spares the epidermis, and has a Grenz zone. As the disease progresses, it frequently extends into the subcutaneous layer but spares the adnexal structures[1]. In addition, the infiltration has a dense diffuse or nodular pattern. At high magnification, the tumor cells are characterized by a monomophic population of small to medium-sized cells with irregular nuclear contours, fine to evenly dispersed chromatin, various-sized or indistinct nucleoli, and scant to moderate amounts of cytoplasm without granules[4]. Characteristic extravasated RBCs responsible for bruise-like clinical manifestations are frequent, and mitoses are occasionally observed[1]. In our cases, all of the biopsies revealed typical features of BPDCN; however, the patients 5 and 6 additionally showed extraordinary findings such as infiltration along the adnexa or fibrotic changes in collagen.

On immunohistochemistry, BPDCN cells typically express a positive reaction to CD4, CD56, and CD123. Of note,

staining for CD123 is typically strong, whereas that for CD4 and CD56 can be weak in some cases[19,20]. The assessment of newer pDC-associated antigens, such as T-cell leukemia/lymphoma 1 (TCL1) and B-cell leukemia/lymphoma 11A (BCL11A) on immunohistochemical studies and blood dendritic cell antigen (BDCA)-2, BDCA-3, and BDCA-14 on flow cytometric analysis are potentially diagnostic for BPDCN[1,4,21]. In contrast, tumor cells are usually negative for lineage-specific antigens of T-cells (CD3 and CD5), B-cells (CD19, CD20, and CD79), myeloid cells (MPO, CD13, and CD117), and NK cells (CD16 and CD57). However, a few markers of T-cells (CD2 and CD7) and myeloid cells (CD33) have been found frequently in tumor cells of BPDCN[4,18]. Moreover, CD68, a marker typically expressed by granulocytes and histiocytes, as well as by normal pDCs, is expressed in 50% of BPDCN cases[4]. TdT, a key antigen for precursor lymphoid cells is positive in one-third to one-half of cases[4]. Finally, BPDCN is negative for Epstein-Barr virus, unlike most true NK cell malignancies[1]. In the present report, immunophenotyping revealed that CD4, CD56, and CD123 were positive in all patients. These results were consistent with BPDCN, and there was no exceptional case.

Previous studies have described some karyotypic abnormalities. The representative chromosomal abnormalities are 5q21 or 5q34 (72%), 12p13 (64%), 13q13-21 (64%), 6q23 (50%), 15q (43%), and complete deletions of chromosome 9 (28%)[22]. In addition, the gene expression profile of BPDCN showed recurrent deletions of 4q34, 9p13-p11, 9q12-q34, and 13q12-q31, which contain tumor suppressor genes (*Rb1* and *LATS2*) with diminished expression, as well as elevated expression of the oncogenes *HES6*, *RUNX2*, and *FLT3*[23]. A recent gene expression study showed loss of the cell-cycle genes *CDKN1B*, *CDKN2A*, and *TP53*[24]. Among our cases, patient 4 had a deletion of 13q12-q22 included in the characteristic gene expression of BPDCN, as mentioned above. In contrast, the other patients did not show any major chromosomal abnormalities.

The clinical course of BPDCN is aggressive with a median survival of 12～14 months, regardless of the initial presentation[4]. However, owing to its rarity and only recent recognition as a distinct entity, there is no standardized therapeutic strategy for BPDCN. Most patients are treated with a variety of intensive combination CTx regimens, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) or hyper-CVAD (combination of course A [cyclophosphamide, vincristine, doxorubicin, dexamethasone] and course B [methotrexate and cytarabine], in an alternating fashion). Patients usually achieve resolution of the initial symptoms with the initial CTx[1]. However, the disease often relapses, and the relapsed disease is generally resistant to the CTx agents previously used[4]. Roos-Weil et al.[25] demonstrated that high-dose CTx followed by allogeneic stem cell transplantation (SCT) from related and unrelated donors could provide durable disease control in up to 50% of patients.

In contrast to that in adults, BPDCN in pediatric patients is clinically less aggressive, and show good response to acute lymphoblastic leukemia-type CTx[14]. Other authors suggested that the best long-term prognosis for relapse-free survival is expected in pediatric patients who ultimately underwent allogeneic BM transplantation after a CTx-induced remission[26,27]. Furthermore, the outcomes were more favorable in cases that lacked cutaneous lesions at presentation[14]. However, the prognostic significance of cutaneous involvement is debatable in adult patients[4,7,10,28,29]. In our cases, the median PFS revealed favorable outcomes in patients with cutaneous involvement; however, the median OS showed the opposite result. However, most of the patients are still alive until now, and these interpretations might be limited. Notably, patient 6, who lacked skin involvement at the initial presentation, showed a relatively long survival. In addition, patient 1, who had skin involvement exclusively, showed a longer survival than patient 2, who had blastic involvement, LN, and BM disease. Furthermore, patients 1, 2, 5, and 7 had achieved CR after the initial CTx. However, they showed relapse 3～12 months later. Especially, patient 2, who had no skin involvement at the initial presentation, showed early relapse and rapid progression despite receiving salvage CTx and autologous PBSCT.

Our study has some limitations. First, only a few patients were enrolled and analyzed. Owing to the small number of patients, it was difficult to carry out statistical analysis and a comparative study. Secondly, because of the retrospective design, the evaluation or follow-up of patients was not equivalent to each other. In addition, recently introduced diagnostic markers such as TCL1, BCL11A, BDCA-2, BDCA-4, and BDCA-14 were not examined. Especially, TdT staining was performed in only three patients. In fact, it was suggested that a high TdT expression (>50%) is associated with a favorable prognosis[29,30]. However, we could not investigate the prognosis with only the three patients. Finally, four patients were still alive at the time of the last follow-up; therefore, careful attention is needed in interpreting the OS.

In conclusion, this report of seven cases of BPDCN in Korea, despite the small number of patients, might provide information about the clinical and histopathological characteristics of this neoplasm. As is well known, early diagnosis and appropriate treatment of BPDCN is crucial to

improve the prognosis. Accordingly, both dermatologists and hemato-oncologists should be aware of this rare entity when confronted with unfamiliar skin lesions and hematological abnormalities. Notably, most of the patients in the present study showed skin manifestations as a sign of relapse. Therefore, it is important to carefully check the skin of the patients after treatment. In addition, in the treatment outcome, it was remarkable that all of the patients showed a high frequency of relapse after multiagent CTx without SCT, and underwent various courses regardless of the cutaneous involvement at the initial presentation. Further studies are needed to recognize the prognostic factors and establish the optimal treatment. Finally, we expect that this study would contribute to future studies such as meta-analyses, by introducing additional Asian cases.

ACKNOWLEDGMENT

We thank the pathologist who assisted in the diagnosis, Young-Hyeh Ko, M.D. (Department of Pathology, Samsung Medical Center), and the hemato-oncologists who provided further evaluation and treatment, Seok-Jin Kim, M.D., Chul-Won Jung, M.D., and Won-Seog Kim, M.D. (Department of Internal Medicine, Samsung Medical Center).
