

## LETTER TO THE EDITOR

# RNA-seq-driven expression analysis to investigate cardiovascular disease genes with associated phenotypes among atrial fibrillation patients

To the Editor

Atrial fibrillation (AF) is defined as the high-frequency excitation of the atrium, resulting in both dyssynchronous atrial contraction and the irregularity of ventricular excitation.<sup>1</sup> According to its condition, AF disease is divided into two sub-types: paroxysmal and persistent. In contrast to persistent AF, paroxysmal AF is diagnosed in the first phase of the disease, which later progresses to persistent AF.<sup>1</sup> Furthermore, AF includes risk factors such as obesity, diabetes, smoking and a sedentary lifestyle and is prevalent in the older males of European ancestry. Previous studies have shown that both heart failure (HF) and cardiovascular diseases (CVD) contribute to an increased risk of AF.<sup>1</sup> In this study, we investigated genes responsible for AF with sub-disease groups through transcriptomic analysis (Additional file 1: High-resolution figures). It was conducted as a continuation of our thorough CVD research focusing on HF performed on 61 CVD patients (Sample IDs: 1058–1118) and 10 patients without CVD (Control IDs: 648–658) (Additional file 2: population details). When grouped by gender and race, there were 40 males and 21 females, 42 Whites, 7 Blacks (Blacks or African Americans), 1 Asian, 1 Decline to Answer, 2 others, and 8 NA (Table 1 and Figure 1A). Peripheral blood samples were used for RNA extraction, and sequencing was performed using Illumina NovaSeq 6000-S4 to assess the RNA quality.<sup>2</sup> An efficient data management system (PROMIS-PCR) with data extraction, transfer and loader system (ETL), created by the authors,<sup>3</sup> was used for patient recruitment and consent tracking as well as dealing with the multi-omics data, respectively.<sup>4</sup> We also created a publicly available gene-disease database, PAS-Gen, which includes over 59 000 protein-coding and non-coding genes, and over 90 000 classified gene-disease associations, to ease the gene-disease visualization for researchers, medical practitioners and pharmacists.

First, the transcriptomic data analysis involved the development of an RNA-seq processing pipeline that contained four operating parts: (I) data pre-processing, (II) data quality checking, (III) data storage and management and (IV) data visualization (Additional file 1: High-resolution figures).<sup>2</sup> The analysis of transcripts per million (TPM) was performed to normalize the RNA-seq data by using the visualizing genes with disease-causing variants environment with the findable, accessible, intelligent and reproducible approach (Additional file 4: AF analysis - gene expression data). It reveals all genes annotated with their associated clinical AF phenotype using gene-disease association.<sup>2,5</sup> This expression analysis was expanded to visualize the classification of protein- and non-coding genes in detail as gender- and race-based. First, we looked across the AF-annotated genes to identify protein- and non-coding genes together and found 71 genes related to AF and relative diseases (Additional file 3: Complete Gene List). Next, we observed expression in protein-coding genes and found 22 genes associated with direct and relative AF diseases, which are denominated as AF phenotypes (*SCN1B*, *NPPA-AS1*, *KCNQ1*, *KCNE1*, *VKORC1*, *ATF7*, *KCNH2*, *SELP*, *PDE4D*, *ACE*, *PRKAR1B*, *NUP155*, *CYP4F2*, *ABCC9*, *KCNJ2-AS1*, *CFAP20*, *KCNJ2*, *MYBPC3*, *KCNE3*, *PF4*, *PPBP*, *MYL4*) (Figure 1B and Table 2). After the initial analysis, differential gene expression analysis was implemented to further investigate AF genes. Of the protein-coding genes, seven AF-associated genes (*MYL4*, *PPBP*, *PF4*, *KCNE3*, *VKORC1*, *KCNQ1* and *CYP4F2*) showed differentially regulated expression (Figure 1C). A previous study has reported some of these genes (*GJA5*, *KCNA5*, *KCNE2*, *KCNJ2*, *KCNQ1*, *KCNH2*, *NPPA* and *SCN5A*) as novel genes for familial AF in the absence of mutations, whereas mutations in *MYL4* have been strongly associated with AF disease in humans.<sup>6</sup>

Note: This table includes patient ID, gender (40 males and 21 females), age and race (42 White, 7 Black: Black or African American, 1 Asian, 1 declined to answer, and 8 NA). Samples 1058–1118 were obtained from CVD patients, whereas samples 648–658 were obtained from healthy individuals. The age of healthy individuals is not available.

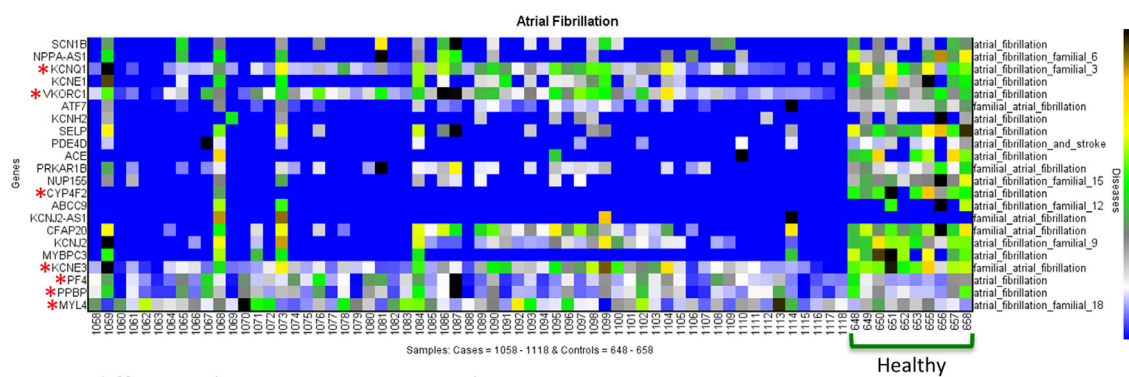

Abbreviations: CVD, cardiovascular diseases; NA, not available.

With a deeper investigation of the normalized expression analysis, we found that *PF4*, *PPBP*, *MYL4*, *KCNE3*, *VKORC1*, *KCNQ1* and *CYP4F2* genes are highly expressed in AF (Figure 1B) with relative diseases as AF phenotypes; AF (both for *PF4* and *PPBP*); AF familial 18; familial AF, AF, AF familial 3, AF, respectively (Additional file 5: Information about AF phenotypes). The phenotypes represent different subsets of how the disease presents when it is inherited based on the gene of interest. Additionally, these findings were supported by another study in which two long non-coding RNAs genes were found to interact with protein-coding genes associated with AF.<sup>7</sup> A subsequent analysis was performed based on two groupings: race- and gender-based. The race-based analysis involved Black, White and all other races in which *PF4*, *PPBP* and

ENSG00000123700	KCNJ2	Protein coding	Atrial fibrillation familial 9
ENSG00000134571	MYBPC3	Protein coding	Atrial fibrillation
ENSG00000175538	KCNE3	Protein coding	Familial atrial fibrillation
ENSG00000163737	PF4	Protein coding	Atrial fibrillation
ENSG00000163736	PPBP	Protein coding	Atrial fibrillation
ENSG00000198336	MYL4	Protein coding	Atrial fibrillation familial 18

Note: This table includes the ENSG ID, gene name, category and disease associated with that gene.

*MYL4* were found to be highly expressed protein-coding genes in AF in all different race groups (Figure 2A–C). Although *KCN3* appeared in the analysis, it did not show consistent expression across the patients. In addition, the *PPBP* gene, which is one of the three immune-related genes (*CXCL12*, *CCL4*), has been found to have a positive relationship with the infiltration of immune cells (e.g. neutrophils, plasma cells and resting dendritic cells) and plays a role in the development of AF disease.<sup>8</sup> Furthermore, the gene expression analysis based on gender segregation showed similar results, with *PF4*, *PPBP* and *MYL4* genes as highly expressed with AF disease in both female and male groups (Figure 2D,E).

In summary, we performed the systematic transcriptomic characterization of AF-associated genes. Our findings report three highly expressed genes and their associated diseases as AF phenotypes; *PF4*: AF; *PPBP*: AF and *MYL4*: AF familial 18, with a similar expression pattern across races and genders. Moreover, when we compared the genes associated with HF from our previous CVD/HF study<sup>2</sup> with those associated with AF, we discovered that two genes (*ACE* and *MYBPC3*) were associated with both diseases (HF and AF). These findings are valuable for future research studies as they signify the potential to

further investigate these genes for mutations and disease-specific variants. This will provide a new path focusing on a more personalized approach to therapy and treatment. In the future, we seek to evaluate the causal basis for AF by moving beyond the one gene-one disease model through the integration of the expressed genome, characterization of mutations derived from genomic signatures and mapping them on phenotypic traits in the electronic medical records. We aim to contribute to the paradigm shift in the application and interpretation of genetic and genomically informed medicine for AF, moving from a deterministic conceptualization to a probabilistic interpretation of genetic risk. This will support diagnostic and preventive care delivery strategies beyond traditional symptom-driven, disease-causal medical practice. We aim to construct machine learning models to identify a baseline transcriptional signature highly predictive of response across these indications.<sup>9</sup> This might accelerate our ability to leverage and extend the information contained within the original data and to model patient-specific genomics and clinical data for significant transcriptional correlations, highlighting the association of genetic variants to clinical outcomes of treatment in AF and other CVD.<sup>5,9,10</sup>
