Effects of mixed agro-residues (corn crop waste) on lignin-degrading enzyme activities, growth, and quality of *Lentinula edodes*

 Shuai Xu,^a Fei Wang,^a Yongping Fu,^a Dan Li,^a Xiaozhong Sun,^b Changtian Li,^a Bing Song[✉]*^a and Yu Li*^a

Using agro-residues in bioreactors to produce mushrooms is an important component of eco-agriculture. Here, we tested the cultivation of *Lentinula edodes* with corn cob (CC) and corn straw (CS), and then evaluated the resulting enzyme activities, agronomic traits, textures and nutrient compositions of mushrooms. Laccase (T1 formula, 3.26 g U⁻¹) and carboxymethyl cellulase (T3 formula, 1.01 g U⁻¹) activities were the highest at the time for a complete substrate colonization stage (TCSC), while acidic xylanase activity was the highest (CK formula, 4.05 g U⁻¹) in the mushroom block to color-turned (TMBCT) stage. The biological efficiency of growth on the T6 formula was 8.82% higher than growth on the CK formula, wherein the low C/N ratio of the substrate had an obvious negative effect on yield while the mass ratio of pileus (MRP) of fruiting bodies did not change with mixed substrates. No significant differences were observed in mineral composition for CK formulas, but corn crop waste (CCW) formulas exhibited more optimal nutritional contents. A formula containing more corn cob and sawdust (SD) (sum of at least 70%) as the substrate can produce fruiting bodies with good hardness. These results indicate that the use of corn cobs as the main ingredient, mixed with sawdust and corn straw to grow *L. edodes* provides a more efficient use of agro-residues for growth. Thus, mixed agro-residue formulas have exceptional advantages in texture, nutrition of fruiting bodies, and yields.

1. Introduction

Fermentation activity is a product of the natural development of human civilization.¹ Macrofungi are very important species that use mycelia to undergo solid-state fermentation (SSF) and produce characteristic fruiting bodies.² Indeed, macrofungi grow on every type of organic matter and recycle substrate nutrients. *Lentinula edodes*, commonly known as shiitake mushrooms, are a highly sought after, edible, and valuable mushroom that are widely cultivated in China (10.43 million tons per year), Japan, and South Korea.³ *L. edodes* contains an abundance of eritadenine that can help maintain low blood pressure in humans.⁴ Likewise, vitamin B12 is the only known vitamin that contains metallic elements and is solely synthesized naturally by microorganisms, such as *L. edodes*. Indeed, it can be important for vegetarians to consume *L. edodes*, because vegetables do not contain vitamin B12 and its deficiency can cause anaemia.⁵ In addition, lentinan produced by *L. edodes* exhibits immunopotential effects and can exert anti-tumor

activities by enhancing normal bodily immune functions, although it cannot directly kill tumor cells.⁶

The highest plantation areas of maize exist in North America followed by Asia, Latin America, and Europe. There are over 3000 types of processed products made from maize. Concomitantly, significant amounts of corn crop waste (CCW) are produced from such activities. In China, agro-residues are abandoned to decay in fields or otherwise burned, thereby resulting in major air pollution.^{7,8} However, CCW, like other lignocellulose materials, are excellent substrates that can grow white-rot fungi. At the same time, timber has been strictly controlled by Chinese governments as a forest resource (index number: 000014672/2018-00466). In 2018, the Chinese government amended and implemented regulations to strictly control the utilization of forest resources, which then increased the cost of *L. edodes* cultivation. Thus, the popularization of cultivating shiitake *via* agricultural waste is urgently needed. In addition, the conversion speeds of biomass must be accelerated from scientific theory to application technology. Indeed, several studies have conducted experiments using different types of agricultural wastes to grow mushrooms.⁹⁻¹¹ Nevertheless, traditional methods for selecting formulas have become outdated.

In this study, major agricultural wastes from northeast China including CS (corn straw) and CC (corn cob), were mixed

with sawdust (SD) to grow shiitake mushrooms. The overall aim of the study was to identify variation in enzyme activities and bioconversion efficiencies during SSF with *L. edodes* grown on different CCW formulas, the enzyme secreted by mushroom through the SSF play an interesting role in the detoxification of solid-state waste materials which can be used for different applications according to the circular economy, such as these enzymes could be used in the improvement of fodder quality.¹⁰ To evaluate the inherent differences in growth between straw formulas, several types of data were measured including three enzymatic activities (laccase, carboxymethyl cellulose, and acidic xylanases), texture that is typically used to evaluate food quality in food science,¹² and agronomic character to identify agronomic characteristic differences. The overall approach used here was to evaluate the specific characteristics (morphology and physiology) of mushroom growth to identify optimal approaches for cultivation.

2. Materials and methods

2.1 Mushroom cultivation and preparation

The *L. edodes* strain 135 (cultivated) was obtained from the Agricultural Culture Collection of China (Beijing) (Number: ACCC50903). A stock culture was maintained on substrate comprising 78% sawdust, 20% wheat bran, 1% gypsum, and 1% lime that was incubated for 30 d at 25 °C in the dark. Spawn were stored at 4 °C until further use.⁹

Six different formula were used to grow *L. edodes* comprising corn cob, corn straw, and sawdust, incorporated with a simplex-lattice design. The CK formula comprised 80% sawdust, 18% wheat bran, 1% gypsum, 0.5% lime, and 0.5% sugar.¹³ The moisture content of each formula was maintained at 60% with a natural pH (the pH was 4.5 ± 0.5 after mycelium full colonization of bags). Further, corn cob, corn straw, and sawdust varied in proportion, while the concentrations of auxiliary materials were consistent across treatments (Table 1).

Well-mixed substrates were placed in mushroom bags (2000 g, polyethylene bag 17 cm × 55 cm × 0.03 cm) was then autoclaved at 121 °C for 3 h, and one interior low-pressure polyethylene bag (15 cm × 55 cm × 0.05 cm) was used after inoculated under aseptic conditions.¹⁴

2.2 Enzyme activity assays and the determination of agronomic traits

2.2.1 Enzymatic measurements. Substrate samples (100.00 g, then grate the samples in liquid nitrogen) were taken from inside of the mushroom bags during the time for complete substrate colonization (TCSC) and time for the mushroom block to color-turned (TMBCCT) periods. Additional samples (0.1 g) were taken from mushroom roots during the time for inoculation to harvest (TIH) period to accurately determine changes in enzyme activities in seven formulas. Each culture substrate experiment was repeated in triplicate. Samples were then quickly frozen in liquid nitrogen and stored at −80 °C until further use. Substrates were later thawed at 4 °C and homogenized in ice water bath. Homogenous substrates were then centrifuged at 8000 or 10 000 g for 10 min at 4 °C and the supernatants were used to determine enzyme activity.

The three enzymatic activities were investigated using commercial test kits (Suzhou Comin Biotechnology Company Limited, China) following the manufacturer's instruction. Briefly, laccase activity was determined using the 2,2'-azinobis-(3-ethylbenzthiazoline-6-sulphonate) (ABTS) method for measuring free radical increases.¹⁵ Acidic xylanase activity was measured by evaluating acidic xylanase reduction of xylan to monosaccharides under acidic conditions, resulting in a color-change of 3,5-dinitrosalicylic acid (DNS) with the monosaccharides in aqueous solutions that can then be used to calculate acidic xylanase activity.¹⁶ Cellulase activity was measured using anthrone colorimetry.¹⁷

2.2.2 Harvesting, determination of agronomic traits, and biological efficiency. The inoculated mushroom bags were incubated at 25 °C in the dark and in a clean room under natural conditions until mycelium fully colonized the bags. To generate tumor-shape nodules, incandescent lamps were turned on. Mushroom blocks then turned color and mushroom primordia formed at about 90 days. Mushrooms were harvested from the substrate after removal from the polyethylene bag and maintained at room temperature (20–25 °C) with constant moisture in the range of 75–85%. Three periods of fresh fruiting bodies (first flush, second flush, and third flush) were obtained based on the NY/T 1061-2006 *L. edodes* grade standard, as issued by the Ministry of Agriculture in China.¹⁸ At the end of three harvesting periods at about 120 days, mushroom yields

^a CC: corn cob; CS: corn straw; SD: sawdust.

were recorded to calculate biological efficiencies (BE), wherein $BE (\%) = (\text{weight of fresh mushrooms harvested/substrate dry matter content}) \times 100\%$. Pileus thickness (PT), pileus diameters (PD), stipe lengths (SL) and stipe diameters (SDT) of single fruiting bodies were recorded using a Digital Vernier Caliper. The mass ratio of pileus (MRP) was then calculated as $MRP = \text{weight of pileus/weight of single fruiting body}$.

2.3 Analysis of texture and nutrients

2.3.1 Texture measurements. The pileus of fruiting bodies was cut into 8 cm^3 cubes and stored at $4 \text{ }^\circ\text{C}$ until further use. Hardness (one of the indicators of taste), springiness (recovery-height of pileus between the end of the first bite and the beginning of the second bite), chewiness (the energy required to chew food), and resilience (index of restoration deformation) were selected as the four indices to analyze mushroom qualities. A texture analyzer (TA.XT Plus Texture Analyzer, made by Stable Micro System Company, UK) was used to evaluate the above characteristics with a P35 probe, a pre-test rate of 2 mm s^{-1} , a mid-test rate of 2 mm s^{-1} , a post-test rate of 10 mm s^{-1} , a compression ratio of 40%, a shear induction force of 5 g, and a probe 2 measurement interval of 5 s, with an automatic trigger type.

2.3.2 Primary nutrient and elemental analysis. After harvesting, the fruiting bodies were placed into a drying oven and dried to a constant weight at $50 \text{ }^\circ\text{C}$. The fruiting bodies (100 g) were then pulverized, sieved with a 200 mesh sieve, and stored at $4 \text{ }^\circ\text{C}$ for further use.⁹ Protein concentrations were determined using the Kjeldahl method (Kjeltec™ 8000, Foss, Hilleroed, Denmark)¹⁹ and fatty acid contents were analyzed using a Soxhlet extractor system (Automatic Fats Analyzer, model 2050, Foss, Hilleroed, Denmark). Total sugar was also determined using the Watt and Merrill method and an ultraviolet-visible spectrophotometer (model T6, New Century, Beijing General Instrument Co., Ltd., Beijing, China). Eight trace elements and four heavy metals common to mushroom fruiting bodies were lastly determined using an inductively coupled plasma mass spectrometer (model 7700× ICP-MS, Agilent,

Santa Clara, CA, USA). Further, the amino acids of the dried fruiting body powder were analyzed with an amino acid analyzer (model Hitachi L8900, Hitachi High Technologies America Inc., Schaumburg, IL, USA; ion-exchanged resin). All chemical tests were performed at the Jilin Province Quality Inspection Institute.

3 Results and discussion

3.1 Enzyme activities

Changes in enzymatic activities among different mixture formulations were the highest during the TCSC period, and decreased during TMBCT. Activities were also higher in the third stage, but were still lower than in the first stage. Changes in enzymatic activity among different formulations also varied due to different enzyme types.

Laccase enzymatic activity was much higher than that of acid xylanase and carboxymethyl cellulase in the three growth stages of *L. edodes*. No significant differences in activity were observed among formulations during the same period, although considerable differences were observed among different stages. The highest differences were observed for the T1 formulation, which exhibited an activity of 3.26 U g^{-1} during the first stage and only 0.05 U g^{-1} during the TMBCT stage.

In contrast to laccase, acidic xylanase activities exhibited high variation. Only a few fungi can produce acidic xylanase under acidic conditions to synthesize sugars for growth. The T1, T2, T3, and T4 formula activities were the highest in the TCSC periods, while the T5, T6, and CK formula activities were the highest in the TMBCT stage. The highest activity during the TMBCT stage for the CK formula was 4.05 U g^{-1} , and the lowest was 0.4 U g^{-1} for mushrooms grown on the T2 formula. The higher levels of sawdust and corn cob in the T5, T6, and CK formulas could alter some of the physical and chemical properties in the bags, and thus explain the differences in acid xylanase activity.

Lastly, carboxymethyl cellulase activities behaved similarly to that of laccase. Cellulase high-low curves were observed during the three growth stages of *L. edodes*, but were much

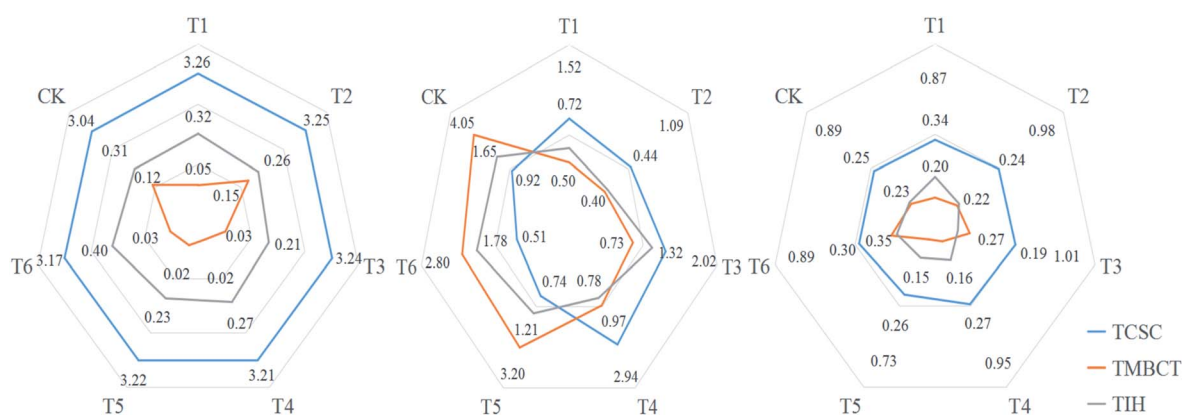

Fig. 1 Radar map of enzymatic activity trends (units: U g^{-1}). Each hexagon-separated unit in the picture is a base-10 logarithm ($Y' = \log 10Y$). The numbers in the figure are the enzymatic activities during the TCSC, TMBCT, and TIH for growth on seven formulas. Laccase activity, acid xylanase activity and carboxymethyl cellulase activity are shown from left to right.

lower than that of laccase. The maximum cellulase activity was observed for the T4 formulation, but was only 0.95 U g^{-1} (Fig. 1).

Evaluation of three enzyme types produced by white rot fungus during SSF,^{20,21} indicated that laccase and carboxymethyl cellulase were important in the first growth stage of *L. edodes*. The above enzymes decompose lignin and cellulose from sawdust and corn straw.^{22,23} During the mycelial growth stage of *L. edodes*, abundant enzymes were secreted to decompose substrates and fuel mycelial growth.²⁴ Mycelium activity was weak during TMBCT indicating that the enzymes produced by mycelium could only be used to maintain living cells and complete physiological structure changes on cell surfaces, bags as nutrient supplier has reached the saturation of mycelial growth. Mycelial activities have become intense for complete the reproductive growth process during TIH, their secreting more laccase and carboxymethyl cellulase to decompose lignocellulose in the substrate to form fruiting bodies. Differences in endocrine enzyme activities in bags obviously differed due to treatment ingredients. T1 (10% CC, 40% CS, 30% SD) formula with the highest corn straw proportion and has the highest laccase activity (3.26 U g^{-1} -TCSC; 0.32 U g^{-1} -TIH), CK formula without straw supplement had the lowest enzyme activity at TCSC stage, its indicated that straw supplement in mixed substrate may lead to more laccase secretion when mycelia flourishing. Acid xylanase activity results showed that the more sawdust in the substrate, the higher the acid xylanase activity at all three stage (CK:80% SD > T4:60% SD > T1:30% SD). Although relation between carboxymethyl cellulases and supplement was not observed that mixture could completely affect the mycelial secretion of *L. edode*.

3.2 Effects of substrates on *L. edodes* fruiting bodies

Agronomic traits were evaluated to identify the CCW decomposition capacity of *L. edodes* for different formulas. BE% trended with formulas as follows: T3 < T1 < T2 < CK < T5 < T4 < T6, wherein the C/N ratios of the T1 and T3 treatments were lower than that of CK (80% SD), while the C/N ratios of T6 (40% CC, 10% CS, and 30% SD) was higher than (8.18%) CK. The PT of the T2 and T3 treatments reached 1.25 cm, with T2, T3, and T5 all exhibiting thicker PT. In addition, the PD values for these three treatments were small. The longest SL value was observed for T3 at 3.26 cm. Nevertheless, statistical analysis indicated

little difference between SL and SDT values among mushrooms grown with different formulas. Pileus weights also varied with single fruiting body sizes and MRP varied independent of formula treatments and generally remained in the range of 0.85 ± 0.1 . Increasing weights of fruiting bodies varied with PT and PD over a particular range (e.g., similar weights exhibited a relationship between high PD and low PT). Thus, the density of *L. edodes* fruiting bodies remained unchanged (Table 2 and Fig. 2).

For statistical analysis of agronomic traits, we focused on comparing the yield distribution and the weight of single fruiting bodies produced by each formula.²⁵ The first and second flush significantly contributed to the ultimate BE% values (Fig. 3). The yield for the T6 formula was slightly higher than those of other formulas in the first and second flushes. Although the yield from the CK formula was not clearly high in the 1st and 2nd flushes, the yield of the 3rd flush was higher than those for the other formulas. The traditional formula

BE (%)	54.77 ± 1.85^c	50.47 ± 1.28^d	53.82 ± 2.02^c	49.94 ± 1.34^d	61.22 ± 1.35^{ab}	59.67 ± 2.26^b	63.59 ± 2.13^a
MRP	0.85	0.86	0.86	0.86	0.86	0.84	0.85

^a BE (%) = (weight of fresh mushrooms harvested/substrate dry matter content) \times 100%. Pileus thickness (PT), pileus diameter (PD), stipe length (SL), stipe diameter (SDT), mass ratio of pileus (MRP) = (weight of pileus/weight of single fruiting body) \times 100%. Different letters (a-d) in the same column and rank indicate significant differences ($P < 0.05$).

Fig. 3 Column map of yield distributions (units: g per bag). Yield distributions for the third, second, and first flushes are shown from top to bottom, respectively. Solid lines in columns shown margins of error. To facilitate comparisons, data are provided in the table below the graph.

exhibited an average yield, while the stalk formula in the experiment exhibited insufficient stamina. It should be noted that the requirements of mushroom cultivation in factories differs from that of farmers. Factories try to obtain high quality mushrooms over short times (*e.g.* the 1st and 2nd flushes), while farmers often look for further benefits and harvest until the 4th flush.²⁶ (Fig. 3).

Suboptimal mushroom sizes produced in straw formulations affects mushroom prices.²⁷ Thus, mushroom size should be considered in addition to yield²⁸ when considering optimal growth formula. The T1 and T2 formulas did not provide the highest yields, but did produce larger fruiting bodies (Fig. 4). The median weight of the fruiting body of fresh mushrooms for the T2 formula was 23.9 g, and only the T4 formula exhibited

^a Different letters (a–d) in the same column and rank indicate significant differences ($P < 0.05$).

a higher value than this. Although the T4, T5 and T6 formulas produced higher yields, the fresh mushroom fruiting bodies produced by these formulas were smaller, and most of the fruiting bodies ranged from 16.8 g and 20 g. The fresh mushroom weights produced by high yield formulas tended to vary little, while the fresh mushroom weights produced by formulas with lower yield varied considerably. Consequently, if large mushrooms are desired by consumers, the T1 and T5 growth formula are the best choices. However, the quality of small mushrooms produced by the T6 formula can often sell at higher prices. Scatter plot analysis revealed the reasons underlying the high yield of T6 (Fig. 4).

Previous study showed that the C/N ratio significantly impacted yields.²⁹ In this research, T1 formula have the lowest BE%, which also have the lowest C/N. However, T2 with the highest C/N yield is not the highest, in the mixture substrate, the T2, T5, T6, appear to be more favorable because they C/N ratio stabilizing at 45.00 ± 1.00 , C/N ratio of mixture should stable within a certain range, and lead to a high BE%. The results of yield distribution showed that supplement for mixture substrate varies from purposes, the traditional formula exhibits advantages in long-term mushroom production capacity in early stages that often meet industrial requirements (costs raise as longer harvesting period). Although the yield of T1, T2 and T5 formulas did not reach the highest level, they did produce larger fruiting bodies (weight of single fresh fruiting body was larger than 60 g). The yield of T4 and T6 formula was higher than others. The scatter plot analysis reveals that the reason for the high yield is that the weight of single fruiting body varies in a small range near the median (scatter plot appears to be enlarged in the middle). The yield in mixture substrate varies inversely with the extent weight (high extent leads to low yield). No interesting results were observed in fruiting bodies traits, because they are intensely vulnerable to changes in environment condition. But, MRP was firstly presented and found that its numerical value stabilized at 0.85 ± 0.01 and did not change with formulas. MRP may respond to changes in strains, MMR as a parameter can apply it to screening high-quality strains. MRP may be the golden ratio in *L. edodes*.

3.3 Effects of substrates on *L. edodes* texture

Texture is an artificial taste recognition property that can help describe food characteristics.³⁰ The formulas produced mushrooms with hardness in the trend of T2 > T4 > T6 > CK > T5 > T3 > T1. The hardness of mushrooms grown with the T1 formula (10% CC, 40% CS, and 30% SD) was only 2744.46 g and 55% lower than those grown with the T2 formula (25% CC, 10% CS, and 45% SD). The springiness index values of mushrooms grown with the CK and T5 formulas were 61.31% and 61.08%, which were higher than mushrooms grown with other formulations. The chewiness of T1 mushrooms was two-fold smaller than CK mushrooms, and springiness varied little (within 5%), indicating that the resilience of fresh mushrooms grown by the T1 formula was the lowest. Hardness and chewiness are two indicators requiring additional attention. Lower chewiness

^a Different letters (a-f) in the same column and rank indicate significant differences ($P < 0.05$). * Essential amino acids.

leads to lower energy consumption. In addition, the hardness of mushrooms is related to the cellulose and lignin content of the growth substrates.³¹ The T1 formula contained the largest amount of corn straw, while the T6 formula contained the highest amount of corn cob. The T4 formula had the highest amount of sawdust besides the traditional formula. The hardness and granularity of sawdust and corn cob materials are much higher than for corn straw, and thus the lignin content of sawdust and corn cob is much higher than that of corn straw. When the mixture formulas only contained 10% corn straw, the hardness of *L. edodes* fruiting bodies was higher (Table 3).

The taste evaluation of SSF products-*L. edodes* – often represent the characteristic of mixture substrates. However, the process is cumbersome and complex, it would be convenient to replace this process with texture test. The small particle size of corn straw affects gas flow in the bags, thereby affecting the complex process of fruiting body formation.³² Consequently, mixed formulas produced mushrooms with higher hardness than did CK. The addition of corn cobs in the bags significantly affected the hardness and resilience of fresh mushrooms. Hardness is one of the main indices to evaluate mushroom growth, because higher hardness leads to better fresh mushroom shapes due to the long-distance transport of *L. edodes*.^{33,34}

3.4 Effects of substrates on the nutritional and mineral compositions of *L. edodes*

The potential for shiitake to enrich mineral elements and nutrients was a primary focus of our study.^{35,36} The T6 formula produced mushrooms with the highest contents of calcium, manganese, and iron and also produced mushrooms with higher contents of other elements except selenium. Iron, copper, and zinc contents were the highest in T5 mushrooms (10% CC, 25% CS, and 45% SD). Sodium, magnesium, and manganese contents were the highest in the CK formula. When planting corn, chemical fertilizers increase the contents of harmful elements in the straw, thereby affecting elemental compositions in the fruiting bodies of mushrooms. CCW had no effect on the harmful element contents within *L. edodes*, but exhibited promotion of zinc and selenium contents, while harmful elements in these mushrooms remained at concentrations lower than the Chinese standard (National Standards of the People's Republic of China, GB 2762-2017).¹⁴

L. edodes fruiting bodies contained low fat contents, but high crude protein and total sugar contents.³⁷ The carbon and nitrogen contents of substrates affect the nutrition of fruiting bodies, and especially the characteristics of sugars and amino acids.¹⁴ Previous studies have shown that as the proportion of corn stalks increased, total and essential amino acid contents first increased and then decreased during mushroom growth.⁹ Sugar content ranged in the trend of: T2 > T4 > T3 > T1 > T5 > T6 > CK. In contrast, crude protein and fat contents did not significantly differ among groups. Although the C/N ratio of the CK formula is suitable for *L. edodes* growth, its carbon and nitrogen contents were low, leading to inferior nutrient compositions in the fruiting bodies compared with stalk

formulas. Amino acid types were the same across formulas, but their abundances varied. Glu, Gly, Val, Ile, Leu, Phe, Lys, His, and Arg content was the highest in T2 mushrooms, while Ser, Glu, Gly, Ala, Val, Met, Ile, Leu, Tyr, Phe, Lys, His, and Arg content was lowest in T6 mushrooms (Table 4).

Metal toxicity in CCW could to be the limiting factors in *L. edodes* cultivation,³⁸ but there was no significant difference between CK and CCW formulas. Carbon content in substrate directly affects total sugar content in fruiting bodies, content of total sugar in CK formula was only 35.60%, 8.72% lower than T2 (38.30%). The content of total sugar in the rest of all CCW formulas stabilized at 37.00% ± 1.00. Carbon and nitrogen content did not affect amino acid contents. Thus, the use of mixed CCS substrates to grow *L. edodes* will not affect the elemental composition of fruiting bodies, and preserves their excellent characteristics including low fat and high protein content, thereby amplifying the advantages of mixture formulations.

4. Conclusions

Cultivation of mushrooms on mixed substrates fully utilizes agro-residues, while excessive straw formulas do not favor the growth of mushrooms due to low C/N ratios. However, when corn cob contents are increased, the resulting CCW formulas exhibit greater advantages than the traditional formula. The specific disadvantages of using CCW is that it cannot maintain yield stabilities and the activities of acid xylanase changes with formulations, while laccase and carboxymethyl cellulase activity trends remain unchanged. Our analyses indicate that the T6 (40% CC, 10% CS, and 30% SD) formula can partially replace the traditional formula and provides an easily available substrate for *L. edodes* cultivation.

Author contributions

SX, FW and YPF conceived and designed the experiments, performed the experiments, analysed the data, wrote the paper, and prepared the figures and/or tables; these authors contributed equally to this work. DL, XZS, and CTL conceived and designed the experiments. BS and YL conceived and designed the experiments, analysed the data, contributed reagents/materials/analysis tools, wrote the paper, prepare figures and/or tables, and reviewed drafts of the paper. All authors read and approved the final manuscript.

Abbreviations

BE%	Biological efficiencies
CC	Corn cob
CS	Corn straw
CCW	Corn crop waste
MRP	The mass ratio of pileus
PD	Pileus diameters
PT	Pileus thickness
SD	Sawdust
SDT	Stipe diameters

SL	Stipe lengths
SSF	Solid-state fermentation
TCSC	Time for complete substrate colonization
TIH	Time for inoculation to harvest
TMBCT	Time for the mushroom block to color-turned

Conflicts of interest

The authors declare that they have no competing interests.

Ethical approval

This article does not contain any studies with animals or human participants performed by any of the authors.

Informed consent

Informed consent was obtained from all individual participants included in the study.
