Objective: The study aimed to evaluate the role of magnetic resonance imaging (MRI) in differentiating between primary benign and malignant soft tissue tumors (STTs).

Patients and Methods: The study was carried out on 110 patients with histopathological diagnoses of STTs. All patients underwent routine MRI before surgery/biopsy at Viet Duc University Hospital or Vietnam National Cancer Hospital, Hanoi, Vietnam, from January 2020 to October 2022. Data on preoperative MRI as well as the clinical features and pathological results of the patients were collected retrospectively. Univariate and multivariate linear regression were used to analyze the relationship between imaging, clinical parameters, and the ability to differentiate malignant from benign STTs.

Results: Among 110 patients (59 men and 51 women), 66 had benign tumors and 44 had malignant tumors. The qualitative values that were significant in distinguishing between benign and malignant STTs were hypointensity on T1-weighted images (T1W; $p < 0.001$), hypointensity on T2-weighted images (T2W; $p = 0.003$), cysts ($p = 0.003$), necrosis ($p < 0.001$), fibrosis ($p = 0.023$), hemorrhage ($p < 0.001$), lobulated margin ($p < 0.001$), ill-defined border ($p < 0.001$), peritumoral edema ($p < 0.001$), vascular involvement ($p < 0.001$), and heterogeneous enhancement ($p < 0.001$). Regarding quantitative values, age ($p = 0.009$), size ($p < 0.001$), T1W signal quantification value ($p = 0.002$), and T2W signal quantification value ($p = 0.007$) showed statistically significant differences between benign and malignant tumors. Multivariate linear regression analysis showed that the combination of peritumoral edema and heterogeneous enhancement was the most valuable in the differential diagnosis of malignant tumors from benign tumors.

Conclusion: MRI is valuable in discriminating between malignant and benign STTs. The presence of cysts, necrosis, hemorrhage, lobulated margin, ill-defined border, peritumoral edema, heterogeneous enhancement, vascular involvement, and T2W hypointensity is suggestive of malignant lesions, especially signs of peritumoral edema and heterogeneous enhancement. Advanced age and large tumor size are also suggestive of soft tissue sarcomas.

Keywords: soft tissue tumors, soft tissue sarcoma, magnetic resonance imaging, tissue characterization, size, prediction

Introduction

Soft tissue tumors (STTs) are a diverse group of lesions arising from non-epithelial (primarily mesenchymal) extra-skeletal tissues of the body, including fat, muscle, tendons, peripheral nerves, blood vessels, and fibers (ligament, fascia).¹ Benign STTs are several times more common than malignancies, with a reported annual clinical incidence of 300 per 100,000.¹ Soft tissue sarcoma (STS) is relatively rare and accounts for only about 1% of cancers.^{2,3} Compared with benign tumors that require only monitoring and sometimes surgery, malignant tumors require surgery and other treatments such as radiotherapy, chemotherapy, and targeted therapy. Delayed detection of STS negatively affects the

treatment outcome and survival prognosis of patients,⁴ so it is extremely important to diagnose the tumor as benign or malignant.

The imaging methods commonly used to evaluate STTs include X-ray, ultrasound, computed tomography, positron emission tomography, and magnetic resonance imaging (MRI). Of these, MRI is considered the gold standard of imaging and is the method of choice to evaluate STTs.⁵ MRI allows for the determination of the anatomy of the tumor, the characterization of the lesion depending on its signal properties, as well as the evaluation of the exact extent of the tumor and its relationship with the surrounding structures. In addition, MRI helps with surgical planning and follow-up after treatment. However, the accurate histopathological diagnosis of STTs is very difficult. A study by Gielen et al⁶ reported that the accurate prediction of diagnostic histology by MRI was only possible in about 50% of cases.

A number of studies have been conducted worldwide on the imaging features of STT on magnetic resonance and the relationships of single or combined features of the tumor, such as age, gender, size, depth, border, signal uniformity, and necrosis, with its benign or malignant nature.^{3,4,7–10} However, the results of these studies are not completely consistent. Therefore, we carried out this study to evaluate the role of magnetic resonance in the differential diagnosis of benign and malignant STTs.

Patients and Methods

Data Collection

This retrospective study included 110 patients with histopathological results regarding primary STTs obtained through biopsy or surgery at Viet Duc University Hospital or Vietnam National Cancer Hospital, Hanoi, Vietnam, from January 2020 to October 2022. All patients underwent routine MRI on 1.5 Tesla or 3.0 Tesla machines before biopsy/surgery to detect STTs. Clinical data were collected from patient records, including sex, age, location, and the histopathological results of the tumors.

MRI Techniques

MRI was performed on a 1.5 Tesla or 3.0 Tesla magnetic resonance machine (Hitachi ECHELON Smart [Hitachi, Japan] 1.5 Tesla and GE SIGNA Pioneer [GE Healthcare, Chicago, IL, USA] 3.0 Tesla). The patients underwent routine MRI with at least one T1-weighted (T1W) sequence, one T2-weighted (T2W) sequence, and one fat-saturated sequence or short tau inversion recovery (STIR) sequence, imaged in at least two planes (axial/coronal/sagittal). Slice thickness ranged from 3mm to 5mm. The field of view (FOV) and surface coils (body or surface coils) varied according to the size and location of the lesion. Contrast injection with gadolinium was then performed intravenously, with a post-injection T1W sequence in at least one plane.

To assess the STTs based on imaging and histologic data, we evaluated the entire series of MRI scans on a picture archiving and communication system workstation 4.7. The images from MRI were retrospectively reviewed by two musculoskeletal radiologists with 10 and 15 years of experience in musculoskeletal radiology who had no previous knowledge of the pathologic diagnosis. Discrepancies in interpretation were addressed by consensus. The parameters were classified into two groups: quantitative and qualitative parameters.

The qualitative imaging features of STTs included hyperintensity on T1W, hypointensity on T2W, cysts, necrosis, calcifications, fibrosis, hemorrhage, septations, margins, borders and peritumoral edema, bone involvement, vascular involvement, and post-contrast enhancement.

The characteristics of hyperintensity on T1W and hypointensity on T2W were defined as increased and decreased signals relative to muscle on the corresponding sequence. The cysts appeared as areas with an irregular margin and usually round or oval morphology and were hypointense on T1W and hyperintense on T2W⁸ (Figure 1A and B). Necrosis was characterized by an area often with ill-defined borders that was hypointense on T1W images and might be hypointense to hyperintense on T2W images, which did not enhance post-injection (Figure 1E and F). Calcification was reflected by a very hypointense signal nodule on both T1W and T2W images.¹¹ Fibrosis was considered present if areas with hypointensity on T1W and T2W and delayed contrast enhancement after contrast injection were present.¹² Hemorrhage showed hyperintensity on T1-weighted images, hypo/hyperintensity on T2W images, which did not drop on

Figure 1 A 28-year-old female patient with synovial sarcoma in the left thigh. The tumor had a heterogeneous signal on sagittal T2W (A) and sagittal T1W (B) and included a cystic component that appeared hyperintense on T2W (A) and hypointense on T1W (B) and a hemorrhagic component that showed a hyperintense signal on T1W (B). Peritumoral edema manifested as hyperintensity on STIR (C). The tumor had a multilobulated margin, a relatively well-defined border with surrounding structures, and many septa inside (D). The necrotic part of the tumor comprised the hypointense portion on T1W images (E), without enhancement after injection (F). The tumor was in contact with the femoral bone but without cortical erosion, bone marrow edema, and involvement of the femoral great vessel on T1 C+ (F).

fat-saturated sequence⁸ (Figure 1B and C). Septations were lines that crossed the lesion and divided it into smaller lobes¹³ (Figure 1D). The margin of the tumors may be lobulated or non-lobulated (Figure 1D). The border of the tumors could be well-defined or ill-defined (Figure 1D). Peritumoral edema was described as an infiltrated, hyperintense T2W and a fat-saturated area around the tumors¹⁴ (Figure 1C). Bone involvement was determined if cortical erosion or bone marrow edema was present adjacent to the tumor (Figure 1F). Vascular involvement was considered present if the tumor was in contact with the blood vessel at an angle >180 degrees or eroding into the blood vessel. Post-contrast enhancement was divided into non-enhancement, homogeneous enhancement (no hyperintensity or uniform hyperintensity compared to pre-contrast images, respectively), and heterogeneous enhancement (uniform hyperintensity compared to pre-contrast images; Figure 1F).

The quantitative imaging features of STTs included diameter, depth, roundness, and signal intensity values on T1W, T2W, and T1 C+. The size of the tumor was calculated as the maximum length of the tumor measured in planes⁹ (Figure 2A). Roundness was the ratio of the maximum width to the length of the tumor (measured on the respective axis;⁹ Figure 2A). Depth was calculated as the smallest distance from the tumor to the skin surface. The quantitative values of the tumor signal on T1W, T2W, and T1W post contrast comprised the average signal of three measurements by regions of interest (ROIs) hand-drawn with an area of 10–20cm² in the solid components of the tumors on the T1W, T2W, and T1W post-contrast sequences respectively, avoiding drawing on adjacent structures and interference components (eg, calcifications, hemorrhages, and cysts; Figure 2B–D).

Statistical Analysis

Statistical data were analyzed using SPSS 20.0 software (IBM Corp., Armonk, New York, USA). Qualitative data were presented as numbers (n) and percentages (%), while quantitative data were presented as mean \pm standard deviation. The differences in the imaging features of benign and malignant STTs were evaluated using the Chi-squared test or Fisher's exact test (if more than 20% of cells had an expected frequency of less than 5). Indexes with p-values <0.05 were included in the multivariate linear regression analysis. A p-value <0.05 was considered statistically significant.

Roundness was the ratio of the maximum width to the length of the tumor (measured on the respective axis). **(B–D)** Illustration showing how to place the ROI of the tumor signal on axial T1W **(B)**, T2W **(C)**, and contrast-enhanced T1W **(D)**.

Results

Diagnosis

The final histopathologic diagnoses of 110 STTs are listed in [Table 1](#) and included 66 benign tumors and 44 malignant tumors. Lipoma, hemangioma, and schwannoma were the most common benign tumors. Synovial sarcoma, undifferentiated pleomorphic sarcoma, liposarcoma, and dermatofibrosarcoma protuberans were the most common malignancies.

Table 1 Histological Types of Included Soft Tissue Tumors

Histologic Diagnosis	Number of Cases
Benign tumors	66
Lipoma	22
Hemangioma	15
Myxoma	1
Giant cell tumor of tendon sheath	7
Myositis ossificans	1
Collagenous fibroma	1
Neurofibroma	6
Schwannoma	10
Pilomatricoma	1
Lymphangioma	1
Lipofibromatosis	1
Malignant tumors	44
Alveolar soft part sarcoma	1
Clear cell sarcoma	1
Dermatofibrosarcoma protuberans	4
Epithelioid sarcoma	2
Lymphoma	1
Liposarcoma	4

(Continued)

Table 1 (Continued).

Histologic Diagnosis	Number of Cases
Malignant schwannoma	2
Synovial sarcoma	10
Leiomyosarcoma	1
Rhabdomyosarcoma	2
Undifferentiated pleomorphic sarcoma	8
Myxofibrosarcoma	2
Myxoinflammatory fibroblastic sarcoma	1
Fibrosarcoma	1
Sarcoma, undifferentiated	4

Regarding the location of the tumor, the benign tumors were most common in the lower extremities (n=28, 42.4%), followed by the head and neck (n=16, 24.2%), the upper extremities (n=15, 23.6%), and trunk (n=7, 10.6%). Malignant tumors were most common in the lower extremities (n=27, 61.4%), followed by the upper extremities (n=11, 2%), trunk (n=5, 11.4%), and head and neck (n=1, 2.3%).

Table 2 lists the results of qualitative values of benign and malignant soft tissue tumors. The qualitative values that were significant in the differential diagnosis of benign and malignant STTs included hypointensity on T1W (p<0.001),

T2W quantitative value	-0.719	0.002*	-0.042	0.106

Note: *Statistically significant difference between benign and malignant lesions.

was 45.82 ± 18.81 ; this difference was statistically significant, with $p=0.00$. Meanwhile, depth and roundness did not differ significantly between benign and malignant STTs.

The quantitative value of the tumor signal on T1W and T2W statistically significantly differed between the two groups of lesions, with $p=0.002$ and 0.007 , respectively. Meanwhile, the value of tumor signal quantification on T1W post contrast was not statistically significantly different.

Table 4 shows the comparison of univariate and multivariate models for the differentiation variable. Univariate linear regression analysis showed that all variables were valuable in differentiating between benign and malignant STTs. Multivariate linear regression analysis showed that the combination of peritumoral edema and heterogeneous enhancement was the most valuable in the differential diagnosis of malignant tumors from benign tumors.

Discussion

STTs are relatively common in clinical practice, but they still pose a significant challenge in clinical and imaging diagnosis. Thanks to advances in multimodal imaging, radiologists have discovered more and more diversity in the morphology, signal, and composition of STTs.

In this study, we found that gender was not related to the incidence of STS. The studies of Kransdorf et al^{3,7} also gave similar results. Significant tissue characteristics suggestive of the malignancy of STTs included cyst, fibrosis, necrosis, hemorrhage, lobulated margin, ill-defined border, peritumoral edema, vessel involvement, and heterogeneous enhancement. This result is consistent with the studies of Chen et al⁸ and Gruber et al.¹⁵ Because malignant cells grow rapidly and require a large supply, malignancies often have vascular proliferation, which results in strong enhancement.¹⁶ A lack of adequate blood supply to tumor areas will lead to necrosis and cystic degeneration. The tumor grows rapidly and invades the small blood vessels; at the same time, the proliferative blood vessels in the tumor often have thin, easily

damaged vessel walls that lead to bleeding in the tumor. Malignant tumors often have lobulated margins and ill-defined borders with adjacent structures due to their invasive nature. Peritumoral edema is suggestive of malignancy as it may reflect infiltrative tumor growth and reactive inflammatory mechanisms. Malignant tumors with a heterogeneous tumor structure and necrotic, cystic, and bleeding components often have heterogeneous enhancement after injection.¹⁶

In this study, calcification, septation, and bone involvement were signs that had no statistical significance in the differential diagnosis of benign and malignant lesions. A possible reason for lack of statistically significant differences in calcification between benign and malignant tumors may be the low accuracy of MRI in detection of calcifications¹⁷ and we were not able to obtain computed tomography or X-ray images of patients. Septation could be seen in both the benign and malignant groups, which is consistent with the study of Chen et al.⁸ Bone involvement was also not a significant parameter in distinguishing between the benign and malignant groups.

We found that the incidence of STS increased with age: the mean age of patients with benign tumors was 36.32 ± 18.13 years, while the mean age of those with malignant tumors was 45.82 ± 18.81 years, consistent with the studies of Kransdorf et al.^{3,7} As with many other cancers, advanced age is a risk factor for cancer,¹⁸ reflecting the duration of exposure to carcinogens and the accumulation of increased cancer risk, as well as genomic instability and the accumulation of DNA damage and mutations over time coupled with disruptions of the DNA repair and cell growth regulation systems.

The size of the STS at the time of detection was also significantly higher than that of the benign lesions. This is consistent with the work of Gruber et al.⁹ This is because malignant tumors grow faster than benign tumors.¹⁹ However, with a size cut-off of 70mm,⁹ 21 patients had benign tumors larger than this threshold and 14 patients had malignant tumors smaller than this threshold. The reason is that the time from the time when tumor began to appear to the time of examination of the patients is different; thus, just the size of the tumor is not enough to accurately determine the benign or malignant nature of the lesion.

The roundness of malignant tumors is greater than that of benign tumors, but the difference in our study was not statistically significant. Meanwhile, Gruber et al study⁹ showed that malignant tumors were significantly more rounded than benign ones, possibly because malignancies often have indistinct borders with neighboring structures, the precise determination of tumor diameters can be misleading, and the heterogeneity of high-resolution imaging measurements affects the results. In this study, depth was also not a meaningful parameter in distinguishing the two groups of lesions, because although malignant tumors tend to develop deeper, benign tumors also have deep-seated types, such as lipomas or deep fibromatoses.

The qualitative and quantitative signal values on T1W of benign tumors were higher than those of malignant tumors, and this difference was statistically significant. This result is contrary to the study of Chen et al.⁸ The reason is probably that in our study, the lipoma/benign tumor ratio was relatively high, and lipoma is hyperintense on T1W. The study of Gruber et al.¹⁵ gave similar results regarding the hyperintensity on T1W of the benign group, which proves that this is not a significant sign in the differential diagnosis of these two groups of lesions. The qualitative and quantitative values of the signal on T2W of malignant tumors were significantly higher than those of the benign group, which is consistent with the studies of Chen et al.⁸ and Gruber et al.¹⁵

Due to the retrospective nature of this study, we were only able to use existing sequences. Besides, it was not possible to collect clinical parameters and the results of other imaging methods. Collecting MRI images from two different centers with different MRI machines resulted in disproportionate image quality, which also affected the outcomes of the study. In addition, compared with other studies, the number of patients in our study was not high, leading to some differences in study results.

Conclusions

MRI is valuable in differentiating malignant from benign STTs. The presence of cysts, necrosis, hemorrhage, lobulated margin, ill-defined border, peritumoral edema, heterogeneous enhancement, vascular involvement, and T2W hypointensity is suggestive of malignant lesions, especially signs of peritumoral edema and heterogeneous enhancement. Advanced age and large tumor size are also suggestive of STS.

Data Sharing Statement

The datasets generated and/or analysed during the current study are not publicly available due to privacy concerns but are available from the corresponding author on reasonable request.

Ethical Approval

This study was approved by Hanoi Medical University Institutional Ethical Review Board and conducted according to the ethical standards of the 1964 Declaration of Helsinki and its later amendments.

Informed Consent

Informed consent was waived for the study's retrospective nature, and the analysis used anonymous clinical data.

International Journal of General Medicine

Dovepress

Publish your work in this journal

The International Journal of General Medicine is an international, peer-reviewed open-access journal that focuses on general and internal medicine, pathogenesis, epidemiology, diagnosis, monitoring and treatment protocols. The journal is characterized by the rapid reporting of reviews, original research and clinical studies across all disease areas. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
