

Epidemiological characteristics of hand, foot, and mouth disease in China

A meta-analysis

Bo Chen, MD^a, Ying Yang, BD^b, Xufeng Xu, MD^a, Haixia Zhao, BD^a, Yi Li, MD^c, Shi Yin, MD^c^b, Yong-Quan Chen, MD^{d,*}

Abstract

Background: To study the epidemic features of hand-foot-mouth disease (HFMD) in mainland China through systematic review and meta-analysis so as to provide evidence for the future prevention and control of HFMD.

Methods: Articles on the epidemic features of HFMD in mainland China, written in English or Chinese and released between January 1, 2015 and January 1, 2020, were searched from English literature databases including Embase, Web of Science, PubMed, Cochrane library, Google academic, and Chinese literature databases including China national knowledge infrastructure (CNKI), Wanfang, and China Biology Medicine (CBM). Papers were selected according to the inclusion and exclusion criteria, and quality scoring was performed. Meta-analysis, sensitivity analysis, and identification of publication bias were finished through STATA version 12.0 software.

Results: A total of 23 articles were included in this study, the total number of cases was 377,083, of which the total number of male cases was 231,798 and the total number of female cases was 145,285, the sex ratio was about 1.6:1, and the incidence of HFMD in China was 1.61% (95% confidence interval [CI]: 1.21%-1.94%). The results of the subgroup analysis showed that the incidence of HFMD in mainland China was the highest in South China, in 2014, in 1-year-old group and in other types of enteroviruses, respectively, with the rate of 3.48% (95% CI: 1.22%-5.73%), 1.81% (95% CI: 1.06%-2.57%), 15.20% (95% CI: 5.00%-2.530%), and 1.83% (95% CI: 1.32%-2.33%), respectively. The differences among the above 4 subgroups were statistically significant (P < .05). There were no publication bias in this study, and the sensitivity analysis results suggested that the meta-analysis results were robust.

Conclusion: There were differences in the distribution of region, time, population, and etiology of HFMD in mainland China. Health departments should adopt key strategies and measures for key populations in key areas to prevent and control the development of HFMD, and improve the ability of pathogen detection and typing in laboratories.

Abbreviations: Cox A16 = coxsackievirus A16, EV71 = human enterovirus 71, HFMD = hand-foot-mouth disease.

Keywords: epidemiological characteristics, hand-foot-mouth disease, meta-analysis

1. Introduction

Hand-foot-mouth disease (HFMD) is a common infectious disease caused by coxsackievirus A16 (Cox A16), human enterovirus 71 (EV71), and other human enterovirus infection.^[1] HFMD is most common in children under 10 years of age, especially children under 5 years of age. The clinical asymptomatic stage of HFMD is

generally maintained at 3 to 5 days, and the course of disease is about 7 to 10 days.^[2] The patient usually has an acute onset, accompanied by herpes on the skin or mucous membrane of the hands, feet, mouth, etc, which contains inflammatory exudate and surrounding redness.^[2] Most patients have mild symptoms, including fever, fatigue, malaise, and respiratory discomfort. A

small number of patients infected with EV71 can cause encephalitis, meningitis, encephalomyelitis, myocarditis, acute delayed paralysis, and even death in severe cases.^[3] HFMD has a variety of pathogenic types, with EV71 infection alternating with CoxAl6 infection as the dominant type leading to the epidemic of HFMD. The clinical manifestations of human infection with the 2 viruses are different. The symptoms caused by CoxA16 are mild and self-limited, while EV71 infection leads to rapid progression of the disease and can be life-threatening in severe cases.^[4] Worldwide, the proportion of HFMD caused by EV71 infection has increased gradually in recent years, and has become the main pathogen of the disease.^[5]

HFMD occurs mainly in children under 3 years of age, and there is a gender difference, with boys slightly higher than girls.^[3] The prevalence of HFMD also varies with different countries, regions, seasons, latitudes, weather, and other factors.^[6] In China, the peak seasons of HFMD in the north and south are slightly different. The first peak of HFMD in the south is from May to June, and the second peak is from September to October. In the north, the incidence is mostly a single peak, with the season from June to September, and the incidence is less in winter. Studies have shown that latitude can affect the prevalence of HFMD to some extent.^[7] The incidence of HFMD is relatively high in low latitudes such as the tropics and temperate zones. In addition, many meteorological factors such as high temperature, low pressure, and abundant precipitation are also closely related to the incidence of HFMD.^[8,9]

At present, more articles have been published describing the prevalence characteristics of HFMD in local areas, while fewer articles have described the prevalence characteristics of HFMD in all over the country. In this study, meta-analysis was used to collect literature on the prevalence of HFMD in mainland China published in the past 5 years, and the prevalence of HFMD in mainland China was comprehensively analyzed in order to provide effective basis for disease prevention and control for relevant health departments.

2. Materials and methods

2.1. Literature retrieval

Literatures related to the prevalence of hand, foot, and mouth in mainland China published between January 1, 2015 and January 1, 2020 were searched in English literature databases including Embase, Web of Science, PubMed, Cochrane library, Google academic, and Chinese literature databases including China national knowledge infrastructure (CNKI), Wanfang, and China Biology Medicine (CBM). The keywords searched in the database are "epidemiological characteristics," "epidemiological study," "epidemiological features," "epidemiological status," "epidemic," "epidemiology," "hand foot mouth disease," "HFMD." Take "China," "Chinese," "mainland" as crowd qualifiers.

2.2. Literature screening

The inclusion criteria of the literature were:

- (1) The study disease was hand, foot, and mouth disease;
- (2) Original literature using cross-sectional research methods;
- (3) The research content includes the 3 distribution of diseases and the distribution of etiology;
- (4) The study population is residents of mainland China;
- (5) Definite study years, total number of respondents, total incidence, and annual incidence.

The exclusion criteria of literature were:

- (1) review, meeting minutes, editorial, etc
- (2) Articles whose quality score is less than 4;
- (3) Unable to download the full text;
- (4) Some data and information in the paper are incomplete, suspicious, or inconsistent.

2.3. Literature quality evaluation

The Agency for Healthcare Research and Quality scale was used to score the selected original literatures in this study.^[10] There are 11 items in the scale, with a full mark of 11. Each item that meets the requirements is denoted as 1 point, while those that do not meet, are unclear or are not involved in the study are denoted as 0 points. 0-3 points, 4-7 points, and 8-11 points are judged as low, medium, and high quality literature, respectively.

2.4. Data extraction

Two researchers completed a literature screening and data extraction, respectively, and then compared the consistency of the selected literature and data extraction. After 2 researchers conducted a data extraction of the included literature respectively, the third researcher compared the data extraction results of the first 2 researchers, and made the final selection after careful consideration of some data with different opinions, so as to complete the data extraction work and develop the best data extraction table. After the opinions of the 3 researchers were unified, an information extraction table was established in Excel software to extract the following information from qualified literature:

- (1) First author, quality score results, study region, study province, and study year;
- (2) The number of cases, the number of people investigated, and the annual incidence;
- (3) Type of prevailing dominant virus.

2.5. Statistical analysis

The point assessment of the incidence rate and the 95% confidence interval of each study were combined for the pooled rates. Cochran Q test and I^2 value were used for qualitative and quantitative analysis of the heterogeneity existing in the studies.^[11] The *P*-value obtained from the Cochran Q test was used to identify whether there was heterogeneity between different studies. If $P \le .1$, it was considered that there was heterogeneity, the random effect model was used for meta-analysis; if P > .1, it was considered that all studies were homogeneous, the fixed effect model was used for meta-analysis. I^2 value is used to represent the heterogeneity between different studies, $0 < I^2 < 50\%$, $50\% \le I^2 \le 75\%$, $I^2 > 75\%$ means low, medium, and high degree of heterogeneity, respectively.

Subgroup analysis was carried out according to study area, epidemic trend, age, and dominant strains. Differences in sample size, quality score, and other characteristics among different studies may affect meta results. In order to identify potential influencing factors, we conducted a sensitive analysis by removing study with small sample size one by one. If there is no significant difference in the combined effect before and after the exclusion of the literature, it means that the results of this meta-analysis are reliable, on the contrary, it means that certain characteristics of an article are potential influencing factors of the research results. Publication bias was assessed using the Begg funnel plot.^[12] Egger linear regression was used to evaluate the symmetry of the funnel plot.^[13] All statistical analyses were performed using STATA version 12.0 software (STATA Corporation, College Station, TX). A *P*-value less than .05 was considered statistically significant.

3. Results

3.1. Literature search results

A total of 2605 articles were retrieved at initial literature searching, and 23 qualified literature were finally included in this meta-analysis.^[14–36] The literature screening flow chart is shown in Figure 1. Of the 23 references included, 1 study received a score of 8, 12 studies received a score of 7, and 10 studies received a score of 6. The basic characteristics of the included literature are shown in Table 1.

3.2. The overall incidence of HFMD in China

In this meta-analysis, the total number of respondents was 312,520,558, and the total number of cases was 377,083. Among them, the total number of male cases was 231,798, and the total number of female cases was 145,285, with a sex ratio of about

1.6:1. The heterogeneity test results showed that P < .1, $I^2 > 50\%$, so the random effect model is used to combine the study results. Meta-analysis results showed that the average incidence of HFMD in all regions of China was (1.68‰, 95% CI: 1.36‰–2.01‰) (Table 2), and the forest plot is shown in Figure 2.

3.3. Regional distribution

Of the literature included in this meta-analysis, there are 4 study groups from the Northwest China, 2 from the Northeast China, 2 from the North China, 3 from the central China, 4 from the Southwest China, 5 from the southern China, 3 from the East China. The heterogeneity test results show that the P < .1, $I^2 >$ 50%, so the random effect model is adopted for meta-analysis. The meta-analysis results showed that the incidence of HFMD in the 7 regions ranged from high to low in South China (3.48‰, 95% CI: 1.22‰-5.73‰), East China (1.86‰, 95% CI: 0‰-4.39‰), Central China (1.84‰, 95% CI: 1.00‰-2.68‰), Southwest China (0.90‰, 95% CI: 0.67‰-1.14‰), Northwest China (0.77‰, 95% CI: 0.11‰-1.43‰), and Northeast China (0.54‰, 95% CI: 0‰-1.11‰), and North China (0.36‰, 95% CI: 0.30‰–0.42‰), among which South China has the highest and North China the lowest. The difference in incidence of HFMD among 7 regions was statistically significant ($\chi^2 = 99480.348$, P < .001) (Table 2). The forest plot is shown in Figure 3.

3.4. Trends from 2014 to 2018

Table 2

Of the literature included in this meta-analysis, there are 15 articles studied the incidence in year of 2014, 17 articles in year of 2015, 15 articles in year of 2016, 6 articles in year of 2017, and 3 articles in year of 2018. The heterogeneity test results showed that $P < .1, I^2 > 50\%$, so the random effect model is adopted for meta-analysis. Meta-analysis results showed that the incidence of HFMD in the 5 years ranged from high to low in 2014 (1.81‰,

Group	Incidence rate	95% CI	Cohran <i>Q</i> test for heterogeneity (<i>P</i> -value)	ľ (%)	Model	Begg P-value	Egger <i>P</i> -value

95% CI: 1.06‰–2.57‰), 2015 (1.62‰, 95% CI: 1.01‰– 2.23‰), 2016 (1.60‰, 95% CI: 1.25‰–1.95‰), 2017 (0.66‰, 95% CI: 0.46‰–0.86‰), 2018 (0.54‰, 95% CI: 0.22‰– 0.85‰). The difference of incidence of HFMD in 5 years was statistically significant (χ^2_{trend} =25367.102, *P* < .001) (Table 2). It was highest in 2014 and lowest in 2018, and showed a decreasing trend of incidence during 2014 to 2018. The forest plot is shown in Figure 4.

3.5. Age distribution

Of the literature included in this meta-analysis, there are 3 literature provided complete data on the age distribution of 0 to 5 years old population, but these 3 literature did not provide complete on the age distribution of over 5 years old, so this meta-analysis only analyzed the age distribution of HFMD of preschoolers under 5 years old. The heterogeneity test results showed that P < .1, $I^2 > 50\%$, so the random effect model is adopted for meta-analysis. Meta-analysis results showed that the incidence of HFMD in the 5 age groups ranged from high to low was in 1-year old (15.20‰, 95% CI: 5.00‰-25.30‰), 3-years old (11.40‰, 95% CI: 4.90‰-17.90‰), 2-years old (10.00‰, 95% CI: 4.10‰-15.90‰), 4-years old (9.00‰, 95% CI: 4.30‰-13.70‰), and 0-years old (3.10‰, 95% CI: 1.20‰-5.00‰) (Table 2). Among them, 1-year old is the highest, 0-years old is the lowest. The incidence of HFMD in children

under 5 years old was statistically significant ($\chi^2 = 667.079$, P < .001).

3.6. Etiological distribution

Of the literature included in this meta-analysis, there are 13 literature with other types of enterovirus as the dominant epidemic strain, 4 literature with Cox A16 (CA16) as the dominant epidemic strain, and 6 literature with EV71 as the dominant epidemic strain. The heterogeneity test results showed that P < .1, $I^2 > 50\%$, so the random effect model is adopted for meta-analysis. The results showed that the incidence of HFMD associated with the 3 dominant epidemic strains was followed by other intestinal viruses (1.83‰, 95% CI: 1.32‰–2.33‰), EV71 (1.72‰, 95% CI: 1.03‰–2.41‰), and Cox A16 (0.73‰, 95% CI: 0.36‰–1.09‰) from high to low (Table 2). When the dominant strains were different, the incidence of HFMD was statistically significant (χ^2 =33277.301, P<.001). The forest plot is shown in Figure 5.

3.7. Sensitivity analysis results

After the exclusion of the small sample study by Hu et al,^[36] the overall incidence of HFMD in mainland China was (1.63‰, 95% CI: 1.29‰–1.98‰), which was not significantly different from the overall incidence of HFMD before the exclusion (1.68‰,

95% CI: 1.36‰–2.01‰). Therefore, the meta-analysis results of this study were stable, and the sample size difference was not a potential influencing factor in this study.

3.8. Publication bias

The *P*-values of Begg test and Egger test were both greater than .05, suggesting that there was no publication bias in this study and that the funnel plot had symmetry. The graphs of the results of Begg test is shown in Figure 6.

4. Discussion

Previous study showed that in the 7 administrative regions of China, Hainan province in the central and southern part of China had the highest average incidence of HFMD, while Xinjiang Province in the northwest had the lowest average incidence of HFMD.^[37] Same as the conclusion of this study that the incidence

of HFMD is the highest in South China, but different from the conclusion of this study that the incidence of HFMD is the lowest in North China. Temperature, humidity, rainfall, and other climatic conditions can promote the reproduction, survival, and transmission of HFMD pathogens to a certain extent, leading to the prevalence and outbreak of HFMD in the population.^[8,9] The coastal tropical and subtropical monsoon climate is the main climate type in South China, which is under the climatic conditions of high temperature, high humidity, and high rainfall. South China is more likely to cause HFMD epidemic compared with North China. Therefore, compared with the north areas, the southeast coastal areas should be better implemented in the prevention and control of HFMD.

Zhao et al^[38] showed that from 2010 to 2015, the incidence trend of HFMD in China showed a peak every 2 years. The research of Xiao et al^[39] showed that the incidence of HFMD in China had an obvious rising trend from 2008 to 2017. This study concluded that the incidence of HFMD declined year by year from 2014 to 2018 in

China. The improvement of the ability to diagnose and distinguish HFMD, the improvement of laboratory pathogen detection ability, the effective implementation of HFMD protection knowledge publicity, and the attention paid by schools, families, and communities to the prevention of HFMD can all contribute to the decrease of the incidence of HFMD year by year.

Ji T et al^[40] showed that people under the age of 5 years old are the key patients of HFMD in China, and some adults can also have HFMD under certain conditions. The conclusion that children aged 1 to 3 years old have the highest incidence level is consistent with this study. Children under 5 years of age have incomplete immune system function and thus becoming the key

population of HFMD. Children in the 0-year group have a certain level of antibodies in their mothers, and children in the 4 to 5 year group can have a certain degree of good hygiene habits, so the 1 to 3 year group is the main population with high incidence of HFMD.

Xu et al^[41] showed that EV71 was the dominant epidemic strain in China from 2008 to 2017, which was different from the conclusion drawn in this study that the dominant epidemic strain was other types of enterovirus. The alternate existence of dominant epidemic strains in different years and the mutation and recombination of viruses over time may lead to different distribution of etiology in different study years. The long-term prevalence and low variability of EV71 and Cox A16 as well as the introduction of EV71 vaccine in China since 2016 have enhanced people's immunity against these 2 viruses and reduced people's susceptibility, thus reducing EV71 and Cox A16 infection to some extent. The relevant health departments should take the initiative to strengthen disease surveillance in the areas with high incidence, such as the coastal areas in the southeast, pay special attention to the population with high incidence, improve the disease surveillance capacity in economically backward areas and improve their disease surveillance equipment and facilities, which will help prevent disease epidemics and outbreaks caused by inadequate disease surveillance.

There are some limitations in this meta-analysis: First, differences in sampling methods, specimen types, sampling detection time interval and detection methods, differences in the ability to detect and report disease cases in rural and urban areas, and differences in the level of economic development may be sources of heterogeneity in this study. In addition, because there are not enough references in the included literature to provide sample size and incidence data of HFMD such as gender distribution, occupational distribution, or age distribution of people over 5 years old in China, this study is unable to provide a complete description of the prevalence of HFMD.

Due to the differences in natural and social factors, the incidence of HFMD in different regions of China is quite different, with the highest incidence in South China and the lowest in Northeast China. The incidence of HFMD decreased year by year from 2014 to 2018. In the under-5 age group, the incidence was highest in the 1-year group and lowest in the 0-year group. Compared with Cox A16 and EV71, regions with other types of enteroviruses as the dominant strains had a higher annual incidence. Based on the available information, predicting

the epidemic trend of the disease in the future and strengthening the surveillance of HFMD in different regions are conducive to the effective prevention and control of HFMD. Although this meta-analysis has some defects, it is still helpful for the follow-up epidemiological research and etiological research of HFMD.
