## abstract

**PURPOSE** Blood or marrow transplantation (BMT) is an integral part of consolidation and/or salvage therapy for patients with acute myeloid leukemia (AML). With the growing population of AML survivors, there is a need to understand the quality of their survival.

**MATERIALS AND METHODS** This multisite study included 1,369 2-year survivors who underwent BMT for AML between 1974 and 2014 at age  $\geq 21$  years and 1,310 siblings. Using Common Terminology Criteria for Adverse Events, severe/life-threatening and fatal chronic health conditions were identified. Multivariable regression analysis was used to compare the risk of severe/life-threatening conditions and health status between survivors and siblings, and to identify risk factors for health conditions among BMT survivors.

**RESULTS** The prevalence of severe/life-threatening conditions was 54.9% in BMT survivors compared with 28.5% in siblings ( $P < .001$ ), yielding 3.8-fold higher odds of severe/life-threatening conditions (95% CI, 3.1 to 4.7) among the BMT survivors. The most prevalent conditions included subsequent neoplasms, diabetes, cataracts, venous thromboembolism, and joint replacement. Survivors were more likely to report poor general health (odds ratio [OR], 3.8; 95% CI, 2.8 to 5.1), activity limitation (OR, 3.7; 95% CI, 3.0 to 4.5), and functional impairment (OR, 2.9; 95% CI, 2.3 to 3.6). Among BMT recipients, the 20-year cumulative incidence of severe/life-threatening/fatal conditions was 68%. History of chronic graft-versus-host disease was associated with a higher risk of pulmonary disease (hazard ratio [HR], 3.1; 95% CI, 1.0 to 9.3), cataract (HR, 2.6; 95% CI, 1.4 to 3.8), and venous thromboembolism (HR, 2.3; 95% CI, 1.3 to 4.7). Relapse-related mortality (RRM) plateaued at 30%, whereas non-RRM increased to 50% at 30 years.

**CONCLUSION** The burden of severe/life-threatening conditions is substantially higher in BMT recipients when compared with an unaffected comparison group, contributing to an increasing incidence of non-RRM over time. Chronic graft-versus-host disease was an important risk factor for severe/life-threatening/fatal conditions among BMT recipients, informing the need for close monitoring to anticipate and manage morbidity.

## INTRODUCTION

Blood or marrow transplantation (BMT) is an established curative treatment option for patients with acute myeloid leukemia (AML).<sup>1,2</sup> Improvement in transplantation strategies, supportive care, and increased donor source availability have led to an increase in the number of patients with AML who are treated with BMT, with notable increases in older recipients.<sup>1-3</sup> In fact, AML is the most common indication for allogeneic BMT, with an estimated 3,500 patients undergoing BMT for AML annually in United States.<sup>2,3</sup> Survival rates after BMT have improved steadily over the past 5 decades, resulting in a growing number of long-term survivors.<sup>1,4</sup> However, these survivors are at high risk of

developing severe or life-threatening chronic health conditions and premature death, attributed to pre-BMT therapeutic exposures, BMT-related conditioning, and persistent post-BMT complications such as chronic graft-versus-host disease (cGVHD).<sup>5-9</sup>

There is a paucity of information regarding the burden of morbidity carried by AML survivors treated with BMT. Previous studies determining morbidity after BMT have been limited to patients who underwent BMT in childhood ( $< 21$  years at BMT),<sup>10-13</sup> or have focused on health-related quality of life and not the burden of morbidity,<sup>14,15</sup> and have not included a non-BMT comparison cohort.<sup>8,10,12,16</sup> We addressed these gaps by using the resources offered by the BMT

## CONTEXT

### Key Objective

To determine the burden of late morbidity and mortality in survivors of acute myeloid leukemia after blood or marrow transplantation (BMT), compare the burden of morbidity with that experienced by a noncancer comparison group, and identify subgroups with increased risk.

### Knowledge Generated

The burden of chronic health conditions was consistently greater in BMT survivors compared with the noncancer comparison group across nearly all health outcomes, contributing to an increasing incidence of non-relapse-related mortality with time. Chronic graft-versus-host disease was an important risk factor for severe/life-threatening/fatal conditions among BMT recipients.

### Relevance

These findings may inform evidence-based health screening recommendations that account for the evolving pattern of morbidity and mortality over time after BMT. Our findings support a long-term need for multidisciplinary management of patients with a history of chronic graft-versus-host disease, setting the stage for screening, early detection, and interventions to mitigate risk of adverse health outcomes.

Survivor Study (BMTSS). Specifically, we examined the burden of morbidity for severe or life-threatening chronic health conditions in adult survivors of AML treated with BMT, compared this burden of morbidity with that experienced by a noncancer comparison group, examined the association between BMT-related risk factors and chronic health conditions among BMT recipients, and described the overall and cause-specific late-mortality conditional on surviving varying lengths of time after BMT.

## MATERIALS AND METHODS

BMTSS is a collaboration between the University of Alabama at Birmingham, City of Hope, and University of Minnesota, and examines the long-term outcomes of individuals who have survived  $\geq 2$  years after BMT performed at the participating institutions between 1974 and 2014. University of Alabama at Birmingham serves as the single institutional review board of record, and institutional review board approval was obtained at all three participating institutions; participants provided written informed consent according to the Declaration of Helsinki. For the current report, eligibility included a single BMT for AML between 1974 and 2014, survival for  $\geq 2$  years after BMT, and age at BMT  $\geq 21$  years. Vital status (alive or deceased) was ascertained as of December 31, 2020, using the following resources: National Death Index Plus, medical records, and institutional long-term follow-up efforts. Information on cause of death was obtained from the National Death Index Plus program and/or medical records. Of the 1,757 eligible patients, 529 had died after surviving  $\geq 2$  years after BMT. Of the 1,228 alive patients, 388 (22.1%) were lost to follow-up or refused study participation, yielding 840 (68.4%) participants followed for a mean of 8.6 years ( $\pm 5.7$ ) after transplant. Compared

with nonparticipants, participants were older at BMT, more likely to be non-Hispanic White, to have bone marrow as the stem-cell source, and to have undergone an unrelated allogeneic transplant, but less likely to have undergone BMT in recent years (Data Supplement, online only).

The noncancer comparison group comprised 1,310 nearest-age siblings of the larger cohort of BMT survivors<sup>17</sup>; selected siblings were therefore not all directly related to the BMT survivors included in the current study. The 840 alive survivors of AML and the 1,310 siblings completed a one-time 255-item BMTSS survey that included questions regarding sociodemographic characteristics (race/ethnicity, educational level, marital status, employment, household income, and insurance status), diagnosis by a health care provider of specific chronic health conditions (Data Supplement) with age at onset, and diagnosis of cGVHD. The BMTSS survey also asked about the participant's health status (poor general health, functional impairment, activity limitation, and anxiety or fear; Data Supplement).<sup>18,19</sup> The reliability and accuracy of the BMTSS questionnaire have been previously established.<sup>20</sup> We used Common Terminology Criteria for Adverse Events version 5.0 to assign a level of severity to each chronic health condition (grades: 1 = mild, 2 = moderate, 3 = severe, 4 = life-threatening/disabling, 5 = fatal; Data Supplement).<sup>7,21</sup> Details regarding donor source (autologous or allogeneic), relapse risk at BMT (high or standard risk), stem-cell source (peripheral blood [PBSC], bone marrow, or cord blood), conditioning therapy (chemotherapy agent [yes/no] and total-body irradiation [TBI; yes/no]), and conditioning intensity (myeloablative, reduced intensity, or nonmyeloablative) were obtained from institutional BMT databases.

## Statistical Analyses

**BMT survivors compared with siblings.** We compared clinical and demographic characteristics of BMT survivors and siblings who completed a questionnaire. We compared the prevalence of any or multiple ( $\geq 2$ ) grade 3 (severe) or 4 (life-threatening) chronic health conditions, as well as the domains of health status between BMT survivors and siblings. For multiple conditions, time to event was defined using the second condition. Missing values were handled as a separate category in the analyses. Multivariable logistic regression was used to adjust for potential confounders between the two groups, and to describe the odds (expressed as odds ratio [OR]) of developing a severe/life-threatening chronic health conditions or poor health status in survivors compared with siblings, with associated 95% CIs. For each multivariable model, we performed stepwise backward variable selection. Variables with  $P$  values  $< .1$  were retained in the final models and are presented in the Data Supplement. For the analyses evaluating odds of reporting poor health status among BMT survivors versus siblings, we created two models, one with and one without chronic health conditions.

**BMT survivors.** Cumulative incidence rates for grade 3-5 chronic health conditions and for the more prevalent conditions ( $> 5\%$ ) were calculated for the 1,369 BMTSS participants who completed a questionnaire ( $n = 840$ ) or were deceased after surviving  $\geq 2$  years ( $n = 529$ ), treating death due to nonchronic health conditions as a competing risk.<sup>22</sup> Fine-Gray proportional subdistributional hazard models were developed to examine demographic and treatment-related risk factors for individual chronic health conditions; hazard ratios (HRs) with associated 95% CI were used to describe the magnitude of risk. Variables included in the models were selected as above and are provided in the Data Supplement. Recognizing the need to consider the changing practice of BMT over time, we created two multivariable models, one that included treatment era and one that did not. Next, we examined the burden of grades 3-5 conditions among the 1,120 allogeneic BMT recipients (81.8% of overall cohort), stratified by history of cGVHD. Survival estimates were calculated using the Kaplan-Meier method, conditional on increasing lengths of survival (2, 5, 10, 15, and 20 years) after BMT.<sup>23,24</sup> The cumulative incidence of relapse-related (RRM) and non-relapse-related (NRM) mortality were computed by treating non-relapse-related and relapse-related deaths as competing risk, respectively.

Data were analyzed using SAS statistical software (version 9.4, SAS Institute, Inc, Cary, NC). All statistical tests were two-sided, and  $P$  values  $< .05$  were considered statistically significant.

## RESULTS

### Demographic and Clinical Characteristics of Study Participants

The demographic characteristics of the 840 BMT survivors and 1,310 siblings are presented in [Table 1](#). The mean age at study participation (55.9 years  $\nu$  56.2 years) was comparable. Siblings were more likely to be female (60.3%  $\nu$  52.1%,  $P < .001$ ), non-Hispanic White (87.6%  $\nu$  75.0%,  $P < .001$ ), college graduates (55.0%  $\nu$  46.7%,  $P < .001$ ), and have an annual household income  $> \$20,000$  US dollars (84.6%  $\nu$  77.0%,  $P < .001$ ).

Disease and transplantation characteristics of the 1,369 BMT recipients are presented in [Table 1](#). The mean age ( $\pm$  standard deviation) at BMT was 44.6 years ( $\pm$  12.8), and the mean interval between BMT and questionnaire completion or death was 8.2 years ( $\pm$  6.3). The majority (86.1%) of the cohort had received allogeneic BMT (50.9% related and 49.1% unrelated). Overall, 52.4% of the survivors underwent nonmyeloablative or reduced-intensity conditioning, and the most frequently used regimen was melphalan-fludarabine-based (51.0%), followed by a TBI-based regimen (38.7%). PBSCs were used in 66.3% of survivors, and 62.7% were considered at low risk of relapse at BMT. Two thirds (67.6%) of the allogeneic BMT recipients carried a history of cGVHD.

### Burden of Morbidity and Poor Health Status in BMT Survivors Versus Siblings

As shown in the Data Supplement, the prevalence of having any or multiple ( $\geq 2$ ) grade 3 or 4 chronic health conditions was significantly greater in survivors compared with siblings (any condition: 54.9%  $\nu$  28.5%,  $P < .001$ ; multiple conditions: 23.9%  $\nu$  7.8%,  $P < .001$ ). BMT survivors had higher odds of developing a grade 3 or 4 chronic health condition (OR, 3.8; 95% CI, 3.1 to 4.7), multiple grade 3 or 4 conditions (OR, 4.3; 95% CI, 3.3 to 5.6), subsequent malignant neoplasm (SMN; OR, 16.9; 95% CI, 11.5 to 24.8), diabetes (OR, 4.6; 95% CI, 2.8 to 7.5), venous thromboembolism (OR, 3.5; 95% CI, 2.3 to 5.2), cataracts (OR, 2.8; 95% CI, 2.1 to 3.8), or undergo joint replacements (OR, 1.5; 95% CI, 1.1 to 2.1) compared with siblings. Furthermore, survivors were significantly more likely to report poor general health (OR, 3.8; 95% CI, 2.8 to 5.1), functional impairment (OR, 2.9; 95% CI, 2.3 to 3.6), activity limitation (OR, 3.7; 95% CI, 3.0 to 4.5), pain (OR, 2.2; 95% CI, 1.7 to 2.7), and anxiety or fears (OR, 2.4; 95% CI, 1.8 to 3.1; [Table 2](#)). These differences were attenuated but remained statistically significant when the model was adjusted for chronic health conditions ([Table 2](#)).

### Morbidity in BMT Recipients

The 10-year cumulative incidence of severe, life-threatening, or fatal (grades 3-5) chronic health conditions was 55% after BMT ([Fig 1](#)). The 10-year cumulative incidence was highest for SMNs (29.5%), followed by

<sup>b</sup>T-test.

<sup>c</sup>Chi-squared test.

<sup>d</sup>Alive or deceased  $\geq$  2 years after BMT.

<sup>e</sup>For alive, time from BMT to survey completion; for deceased, time from BMT to death.

<sup>f</sup>Patients transplanted in first or second complete remission were considered at standard risk for relapse, and all others were considered at high risk.

<sup>g</sup>Limited to 1,179 allogeneic BMT survivors.

cataracts (15.6%), joint replacement (10.1%), venous thromboembolism (8.3%), and diabetes (6.8%; Fig 2). The most frequent SMN types included melanoma or squamous cell carcinoma of the skin (68.9%), breast cancer (6.7%), and colon cancer (1.8%). The latency for chronic health conditions varied, with longer latencies for SMN and cardiovascular diseases (Data Supplement). Compared with bone marrow recipients, PBSC or cord blood recipients were more likely to have a grade 3-5 chronic health condition, multiple conditions, cataracts, diabetes, or venous thromboembolism; individuals at high risk of relapse at BMT were also more likely to report cataracts (Data Supplement). However, these associations were no longer significant when the multivariable model was adjusted for treatment era (Data Supplement). Allogeneic BMT recipients were at increased risk of developing nearly all health outcomes, compared with autologous transplant recipients

(Data Supplement), and this association remained significant for any grade 3-5 chronic health condition, multiple conditions, joint replacement, and cardiovascular disease, irrespective of adjustment for treatment era in the model (Data Supplement).

Among allogeneic BMT recipients, the 10-year incidence of grade 3-5 conditions was significantly higher among those with a history of cGVHD (63.8% v 43.8%,  $P < .001$ , Data Supplement). Multivariable analyses revealed that history of cGVHD was associated with increased risk of grade 3-5 condition (HR, 1.3; 95% CI, 1.0 to 1.6), multiple grade 3-5 conditions (HR, 2.4; 95% CI, 1.6 to 3.5), pulmonary disease (HR, 3.1; 95% CI, 1.0 to 9.3), cataracts (HR, 2.6; 95% CI, 1.4 to 3.8), and venous thromboembolism (HR, 2.3; 95% CI, 1.3 to 4.7; Data Supplement). Patients with cGVHD were more likely to report poor general health (HR, 2.4; 95% CI, 1.5 to 4.1), activity limitation (HR, 2.5; 95% CI,

1.7 to 3.6), pain (OR, 2.0; 95% CI, 1.3 to 3.1), and anxiety or fears (OR, 1.7; 95% CI, 1.0 to 2.9), compared with those without cGVHD.

**Late Mortality in BMT Recipients**

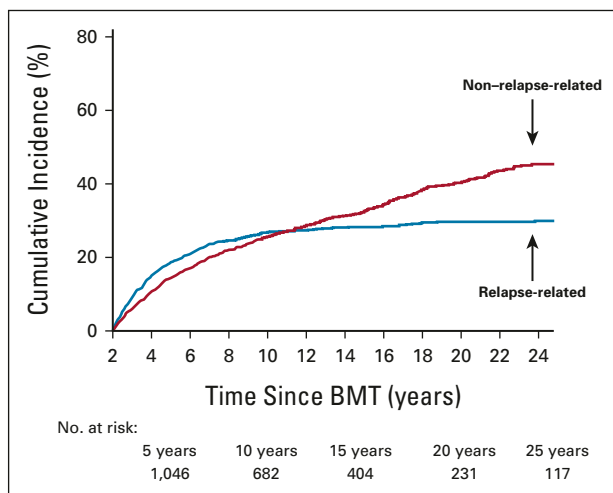

Conditional on having surviving 2 years, the 5-year overall survival for this cohort was 76.4% (Fig 3). There was an improvement in 5-year survival rates conditional on having survived 5 years and 10 years (80.9% and 88.2%, respectively; Fig 3). As seen in Figure 4, the incidence of RRM plateaued at 30%, whereas the incidence of NRM continued to increase, approaching 50% at 30 years and crossing over the RRM rate at 12 years after BMT. Of note, the incidence of late relapse largely mirrored the incidence of RRM in this cohort (Data Supplement). Among 2-year

survivors, the most common causes of death were primary disease (43.8%) and infection (21.3%), whereas the most common causes of death among 15-year and 20-year survivors were SMN (16.5% [15 years] and 21.4% [20 years]) and cardiovascular disease (16.5% [15 years] and 16.7% [20 years]).

**DISCUSSION**

Patients diagnosed with AML have benefited greatly from therapeutic advances over the past 4 decades, resulting in greater utilization of BMT and an overall improvement in survival rates.<sup>1,2</sup> However, it is increasingly recognized that these treatment advances have come at a cost.<sup>5-9,25</sup> We previously reported on the health outcomes of 401 survivors of acute lymphoblastic leukemia (n = 120) or myeloid leukemia (n = 281) who underwent BMT with mostly TBI-based myeloablative conditioning (acute lymphoblastic leukemia: 100%; AML: 86%) between 1974 and 1998 and a sibling comparison group.<sup>26</sup> The current study builds on our previous report, and includes a larger (N = 1,369) and expanded cohort of patients with AML who underwent BMT during a more recent era (71% underwent BMT after 2000), with contemporary approaches (eg, non-TBI-based and/or nonmyeloablative conditioning, PBSC, or cord blood stem-cell source), were older at BMT, and had a longer follow-up after BMT.

This study represents the most comprehensive assessment of health outcomes in the largest cohort of long-term adult survivors of AML treated with BMT. The burden of chronic health conditions remained consistently greater in BMT survivors compared with siblings across nearly all outcomes, and this burden increased with longer follow-up after BMT. The magnitude of risk varied across health

**FIG 4.** Cumulative incidence of cause-specific mortality among BMT survivors. BMT, blood or marrow transplantation.

No. at risk:				
5 years	10 years	15 years	20 years	25 years
1,046	682	404	231	117

outcomes, ranging from 17.0-fold for SMN to 1.5-fold for joint replacement. Importantly, the latency for certain chronic health conditions such as SMN and cardiovascular disease was long (median 5 years after BMT [range, 2-30 years]), with no plateau in incidence over time, emphasizing the need for lifelong vigilance and for consideration of more aggressive screening strategies than what is currently recommended for this population.<sup>27</sup> Nearly one in four BMT survivors rated their health as poor, and half reported significant activity limitations. Although health status was impaired across all domains, the magnitude of impairment was highest for activity limitation, and this was independent of the severity of the chronic health conditions. These findings highlight the increasingly recognized need for specialized, multidisciplinary, long-term follow-up care for AML survivors that incorporates physical function assessments in addition to surveillance for specific chronic health conditions.<sup>5</sup>

By 10 years after BMT, nearly 30% of survivors developed an SMN and 16% developed cataracts. By contrast, in a recent study of 1-year adolescent and young adult (15-39 years at diagnosis) survivors of AML, the 10-year incidence of SMN and cataracts was 4% and 10%, respectively.<sup>10</sup> The difference in the incidence rates between the two studies may be attributable, in part, to the older demographic of our study population and differences in ascertainment of health outcomes. The findings from the current study may provide much-needed insight into the anticipated burden of morbidity in AML survivors, given the steady increase in average age at transplantation for AML over the past 4 decades.<sup>2,3,28</sup>

Allogeneic BMT recipients had a nearly two-fold higher risk of developing a grade 3-5 chronic health conditions, and a three-fold risk of developing multiple conditions, compared with autologous BMT recipients. However, use of autologous BMT, once considered a viable treatment strategy for AML, has steadily declined over time in favor of allogeneic BMT.<sup>1,3</sup> Acknowledging this change in clinical practice, we performed subanalyses that were limited to survivors of allogeneic BMT, with a focus on cGVHD. cGVHD was associated with a 1.3-fold risk of having at least one grade 3-5 conditions and a 2.4-fold risk of having multiple such conditions, likely contributing to worse health status across nearly all domains examined. cGVHD was associated with increased risk of pulmonary disease, cataracts, and venous thromboembolism. These findings are in line with previous studies that have documented the association between cGVHD and/or its treatment and these health outcomes (ie, corticosteroid-associated cataracts,<sup>28,29</sup> inflammation, and/or immobility leading to venous thromboembolism<sup>10,19,21</sup>), and underscore the importance of efforts to reduce the risk of GVHD at the time of BMT (eg, T-cell depletion and use of bone marrow stem-cell source) and continued efforts devoted toward developing treatments to reduce the severity of cGVHD after BMT.

The overall 5-year survival rate conditional on having survived 2 or more years was 76.4%, and there was a steady increase in survival, conditional on having lived at least 5 and 10 years.

There was a modest decline in the 5-year survival rate conditional on surviving 15 years, largely because of the competing risk of NRM, including deaths due to SMN and cardiovascular disease. This is not surprising, given that cancer and cardiovascular diseases are leading causes of aging-related mortality in the United States. Nevertheless, studies examining cause-specific mortality in BMT survivors have shown that the relative risk of death due to these aging-related diseases remains greater than in the general population, even after adjusting for sociodemographic confounders.<sup>23,24,30</sup> We also found a corresponding decline in RRM over time. Similar trends in cause-specific mortality with time from cancer diagnosis have been reported in childhood and adult cancer survivors and support the need to dynamically evaluate mortality risk after BMT.<sup>23,24,30-32</sup>

The findings from this study must be considered in the context of its limitations. We acknowledge differential participation rates by age, race/ethnicity, and certain transplant-related characteristics, which may have affected the generalizability of our findings. BMTSS relies on self-report for measuring chronic health conditions. Thus, this study summarizes the prevalence of and risk factors for chronic health conditions diagnosed by the health care system and communicated to cancer survivors and the noncancer comparison group. The reporting of health conditions is, therefore, a reflection of study participants' access to care, awareness among the health care providers of the risk of long-term complications, and communication of these outcomes to their patients. We have previously shown excellent correlation between medical records and self-reported outcomes, including cGVHD,<sup>20</sup> and are confident that self-report can be used effectively to describe post-treatment complications that are diagnosed as part of routine health care delivery. Importantly, for the current study, we limited our outcomes of interest to those considered severe or life-threatening, which typically require medical or surgical intervention, thus minimizing the risk of recall bias.

In conclusion, this study provides a global assessment of the burden of morbidity in survivors of AML treated with BMT and finds that, compared with unaffected individuals, BMT survivors are at increased risk for severe/life-threatening health-related complications across nearly all domains. The overall burden of chronic conditions increases sharply with longer follow-up, contributing to a rising incidence of nonrelapse mortality. These findings may inform evidence-based health screening recommendations that account for the evolving pattern of morbidity and mortality over time for BMT survivors. Among allogeneic BMT recipients, those with a history of cGVHD were at highest risk of chronic health conditions and for reporting worse health status. These findings support a long-term need for multidisciplinary management of patients with a history of cGVHD, setting the stage for screening, early detection, and interventions to mitigate the risk of adverse health outcomes. The growing population of acute leukemia survivors

treated with BMT (estimated > 40,000 in the United States alone by 2030)<sup>4</sup> makes the development of such strategies imperative, to ensure these survivors live long and healthy lives well after their BMT.
