Abstract

Background: General health checks are an established component of preventive health care in many countries. Declining participation rates have raised concerns in health care providers. Understanding the reasons for attendance and non-attendance is necessary to improve the preventive health care system. The aim of this study was to examine health- and study-related factors associated with university entrants' health check attendance.

Methods: Since 2009, an electronic health questionnaire (eHQ) has been conducted yearly to all Finnish university entrants by the Finnish Student Health Service (FSHS) to screen students for a general health check. The questionnaire comprises 26 questions about health, health habits and studying. The study population consisted of the 3346 entrants from the 2011–2012 academic year who were referred to a health check based on their eHQ responses. The eHQ data were linked with health check attendance information. Multivariable logistic regression was used to study the associations between the questionnaire responses and non-attendance of the health check.

Results: Male sex (OR 1.6, 95% CI 1.4–1.9) and low engagement with studies (OR 1.5, 95% CI 1.2–2.0) were the variables most strongly associated with non-attendance. Having low state of mind was negatively associated with health check non-attendance thus enhanced the health-check attendance (OR 0.6, 95% CI 0.5–0.8).

Conclusions: The results suggest that providing health checks in student health care may serve as a way of reaching students with health concerns. However, motivating males and smokers to attend general health checks continue to be a challenge also in a university student population. That low engagement with studies associates with health check non-attendance points to need to improve collaboration between universities and student health care.

Keywords: Health check, Student health care, Health behavior, Health promotion, Health services research

Introduction

General health checks are an established component of preventive health care in many countries despite the inconclusive evidence of their effects [1, 2]. Declining attendance rates have been a challenge for health care providers [3].

In previous studies in adult populations, the reasons behind health check non-attendance have been diverse. In general, attenders have been found to be older than non-attenders [4]. Males and socioeconomically disadvantaged people have been less likely to attend [5, 6]. Of the health-related reasons, smoking, heavy drinking, physical inactivity, and obesity have been shown to be associated with non-attendance [5, 7]. Further, several health check system related reasons for non-attendance have been de-

scribed, such as suitable timing and the location of the health check provider [8, 9].

Student health services of university students, including preventive and medical care, are provided nationally by the Finnish Student Health Service (FSHS) in Finland. As previously described in depth, the basis of preventive work at the FSHS is a statutory two-phased health examination process provided to all university entrants [10]. The process is targeted to detect risks for study ability early in studies [11] and consists of an electronic health questionnaire (eHQ), a screening tool, followed by a health check if needed [10–12]. Participation in the health examination process is voluntary and free of charge for students and it is their responsibility to make the health check appointment.

Health check attendance has been assessed in adult populations, however, in most cases young adults under 35

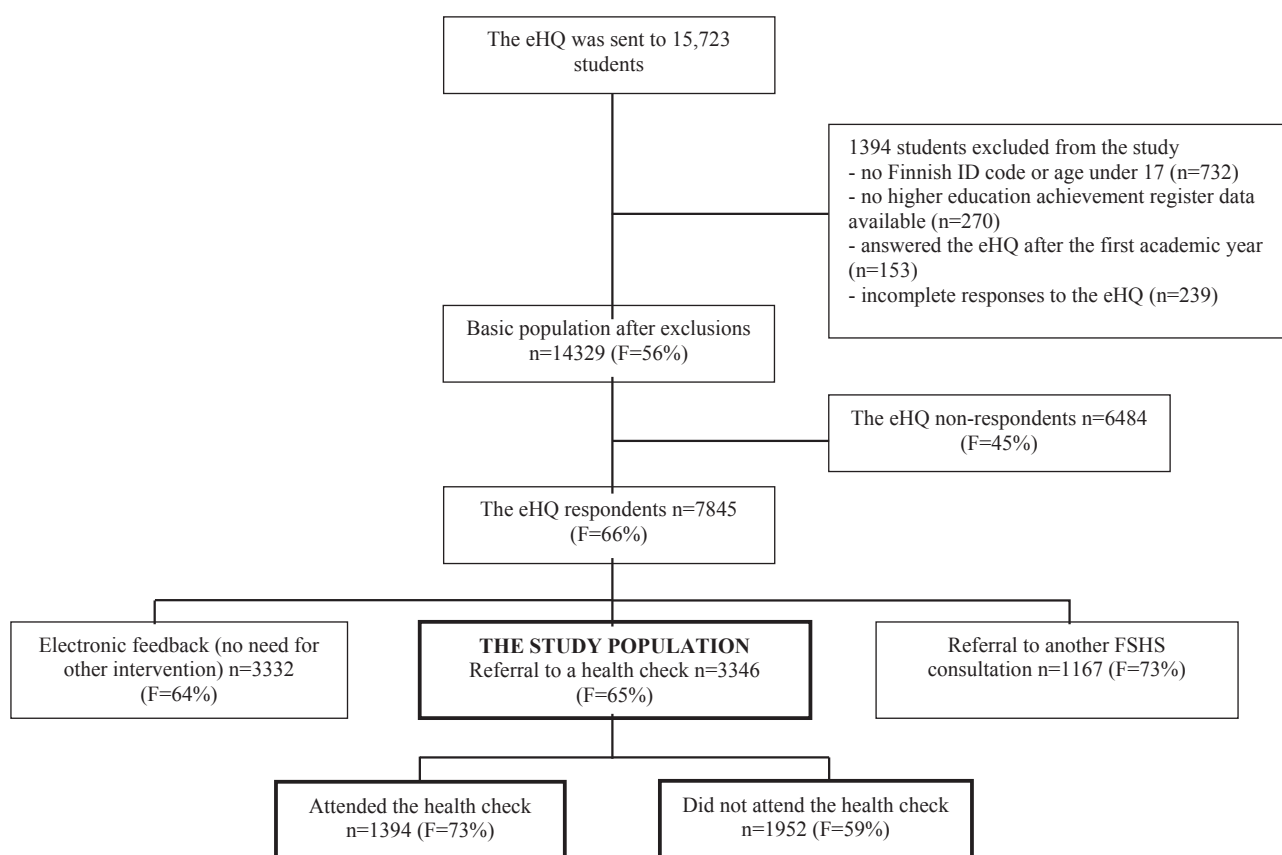

Fig. 1 Proportions of females (F) presented in parentheses for each step of the health examination process.

years have not been included. Specifically, there is lack of evidence about health check attendance of university students. Gaining information about the reasons behind the non-attendance of health checks is especially important in a society, where preventive services are publicly funded and the provision of health checks to university entrants is statutory.

The aim of this study was to describe factors associated with the health check attendance of university entrants. The specific research question was: How are university entrants' responses to the eHQ questions associated with health check non-attendance.

Methods

This was a nationwide register-based cohort study in Finland, the design and methodology of which have been described previously [10]. The study was conducted using data on the health of university entrants produced during the FSHP health examination process. When admitted to a university, students are granted the right to study undergraduate studies followed by graduate studies. The word entrants in this study signifies students admitted to undergraduate studies. The basic population was the national cohort of university entrants from the 2011–2012 academic year in Finland ($n = 15,723$) who were followed for six-years. The final study population in the present study con-

sisted of the 3346 students who were referred to a health check based on their eHQ responses (Fig. 1). The students who attended and did not attend the health check were compared.

The electronic health questionnaire (eHQ)

The eHQ was developed and piloted in 2009 for practical purposes of FSHP [11]. The questionnaire comprised 26 questions about health, social relations, and studying (Additional file 1). The questionnaire was conducted in the two official languages (Finnish and Swedish), and additionally in English. The students received an invitation to respond to the eHQ by email. The email included a link to log in to the web-based eHQ program where they could respond to the questionnaire. The program sent an automated reminder once, two weeks after the initial invitation had been sent. The responses were read and considered by the FSHP public health nurses. Based on the eHQ responses, a nurse guides the student to one of the following interventions: 1) referral to a health check conducted by a public health nurse, 2) referral to an appointment other than a health check, e.g., physiotherapy, or 3) in the case of no need for other interventions, an electronic message to the student to support a healthy lifestyle. The public health nurse gave the feedback in the eHQ program, and the student received an email notification to log in to the eHQ program to check their feedback.

Ten of the eHQ questions had a response scale from -10 to $+10$. Respondents were guided to interpret the scale so that positive numbers suggested a favourable status, and zero (0) suggested a neutral situation, and negative numbers suggested a problematic situation. As the distributions of the responses were highly skewed to the high positive end of the scale, we wanted to examine whether also low positive values indicated a problematic situation. The responses were therefore sorted into three categories for statistical analysis as High (8–10), Medium (0–7) and Low (-10 – -1).

Drug use was assessed by asking: “Have you experimented or used any drugs or taken alcohol and medication at the same time in order to get intoxicated?” The response alternatives were: “never, yes 1–4 times, yes 5 times or more often”. For the statistical analysis, the latter two responses were combined into one “yes” category.

Alcohol use was assessed by asking: “Do you use alcohol?”. Subsequent to the response “yes”, the 10-item Alcohol Use Disorders Identification Test (AUDIT) was presented [13]. AUDIT points were calculated and categorised into four categories according to the World Health Organization (WHO) classification: <8 low risk, 8–15 medium risk, 16–20 high risk and >20 possible alcohol dependence [14].

Age was categorised as in the Eurostudent study and in the Finnish University Students’ Health Survey as follows: 17–21 years, 22–24 years, 25–29 years and 30 years or older [15, 16]. Students reported their height and weight in the eHQ. Body-mass index (BMI) was calculated and categorised following the WHO categorisation: <18.5 (underweight), 18.5–24.99 (normal weight), 25.0–29.99 (overweight), 30–34.99 (obese, Class I), and ≥ 35 (obese, Class II and III) [17].

The eHQ data included register-based information about the students’ faculty of study. For the statistical analyses the faculties were categorised to form the variable “field of study”. The categorisation was based on the classification used in the Finnish University Students’ Health Survey and is in accordance with the fields of study listed by the Ministry of Education and Culture. Faculties were categorised as “other” when they could be included in more than one category.

Data

The eHQ data were obtained from the eHQ register of the FSHS for the 2011–2012 academic year. The intervention chosen by the public health nurse was available from the eHQ data. The information about students’ attendance of the health check was collected from the FSHS medical records. The data were linked by using Finnish personal identity codes [18]. All Finnish citizens and permanent residents have personal identity codes administered by the Digital and Population Data Services Agency, which enables data linkage between the registers and individual-level analyses. The information about the sex of the students was based on the personal identity codes.

Statistical analysis

To describe the data, the frequencies and percentages of each variable were calculated. Chi-squared tests were employed to detect associations between the categorical variables. In cases with continuous non-normally distributed data, the Mann–Whitney-*U*-test was used to detect the differences between groups. A p -value <0.05 was considered to be statistically significant.

The data were analysed with a binary logistic regression model to detect the variables in the eHQ that were statistically significantly associated with health check non-attendance. In the logistic regression models, the odds ratios of the categorical variables were compared against the reference category of each variable, with the exception that the field of study was compared against the mean of all study fields. First, univariate models were created for each associated factor separately. Further, as many of the students may have several risk factors, we used multivariable logistic regression, into which we included all the variables with $p < 0.05$ between the outcome and independent variable. With this model we computed the odds ratios (OR) with 95% confidence intervals (CI), now adjusted for other covariates, including possible confounders. All statistical analyses were carried out using IBM SPSS Statistics for Windows, version 26 (IBM Corp) and R version 3.6.1 (The R Foundation), with package ggplot2.

Results

Of the university entrants who responded to the eHQ ($n = 7845$) 43% were referred to a health check ($n = 3346$) of which at total 58% did not attend (Fig. 1). Table 1 shows the demographics of the students referred to the health check by the health check attendance. Of the students referred to the health check, 68% of men and 53% of women did not attend ($p < 0.001$) (Table 1). There was no difference in age groups between the students who attended and did not attend the health check ($p = 0.056$). The proportion of the non-attendees was highest among law students (66%) and students categorized into the “other” group (74%) and it was the lowest among arts students (42%).

The Table 2 presents the distributions of the eHQ responses, in which there was a statistical difference between the health check non-attendees and attendees. Further, all the distributions are presented in Additional file 2. Of the students who did not attend the health check, 43% got eight (8) points or more in the AUDIT, referring to possible risks of alcohol use. This was statistically higher proportion ($p < 0.001$) compared to the 34% of the attendees. The non-attendees were more often daily or occasional smokers (31%) than the attendees (24%) ($p < 0.001$). Further, there were statistical differences in the frequency of reported chronic diseases ($p = 0.012$) and recurrent symptoms ($p < 0.001$) of which non-attendees reported 24% and 41% while the percentages among attendees were 27% and 52%, respectively. Additionally, of the non-attendees, 11% reported low general health and 12% low usual state of

mind, while the percentages for the attendees were statistically higher, 14% and 17%, respectively.

Table 3 shows unadjusted and adjusted ORs for variables present in the final model of the multivariable logistic regression analysis which describes the associations between the students eHQ responses and the health check non-attendance. Unadjusted and adjusted ORs for all variables in the binary logistic regression models are presented in Additional file 3. The variable with the highest OR for health check non-attendance was the male sex, as males were 1.59 times more likely not to attend the health check when compared to women (OR = 1.59, 95% CI 1.35–1.87) (Table 3). Further, low engagement with studies (OR = 1.54, 95% CI 1.20–1.99) and both daily (OR = 1.30, 95% CI 1.01–1.67) and occasional (OR = 1.30, 95% CI 1.08–1.57) smoking were associated with health check non-attendance. Business and economics (OR = 1.50, 95% CI (1.12–1.99)) and the group other (OR = 1.57, 95% CI (1.03–2.41)) were the fields of study with the highest OR for non-attendance. Conversely, indicated willingness to discuss about sexual health (OR = 0.67, 95% CI (0.56–0.81)) or other matters (OR = 0.55, 95% CI (0.47–0.64)), low usual state of mind (OR = 0.64, 95% CI (0.50–0.82)), and the presence of persistent or recurrent symptoms (OR = 0.77, 95% CI (0.67–0.89)) were negatively associated with health check non-attendance.

Discussion

In this study, low engagement with studies, smoking and

male sex were associated with health check non-attendance. Low usual state of mind, the presence of persistent or recurrent symptoms and indicated willingness to discuss with a health care professional were negatively associated with health check non-attendance, thus enhanced the health check attendance in student health care.

This study found that university entrants' low engagement with studies was associated with non-attendance of the health check in student health care, a novel finding. It is possible that entrants with low engagement with studies did not find the health check respond to their needs. In the Finnish University Students' Health Survey students have repeatedly reported a need for help to deal with stress and time management [15], factors influencing study engagement [19, 20]. As these issues have been responsibility of student counselling, and less of student health care, there seems to be a need for improving collaboration.

The present results support previous findings about the association between smoking and non-attendance of health checks [4, 5]. In the university student population, smoking has been associated with several risk factors like binge drinking, drug consumption, and low belief ratings in the health benefits of not smoking [21, 22]. Adolescence is a transitional phase in which the opportunities for health promotion can be great, highlighting the importance of motivating young adult smokers to attend the health checks.

Support for previous findings on male sex associating with non-attendance of health checks is presented in this study [23–25]. In a review, male-dominant barriers to at-

tend health screening included heterosexual self-presentation, avoidance of femininity and lack of time [24]. Another systematic review stated that there is little published evidence on how to improve men's uptake of health promotion services [25].

The present results indicate that having recurrent symptoms or low usual state of mind are negatively associated with health check non-attendance in university student population. These findings are contradictory to previous research conducted in older adult populations, where non-attenders in routine health checks appeared to have

greater clinical needs [4, 26]. It is possible that university students' help seeking behaviour differs from other adult populations.

Poor mental health of university students and young people in general has been a growing public concern [27–29]. It was an encouraging finding that students with low usual state of mind were 1.6 times more likely to attend the health check than those with a good state of mind. This is supported by one previous research which has shown that students who participate in the first stage of the health examination process of FSHS, i.e. respond to

the eHQ, have more health problems, especially mental health issues, than non-participants [30]. However, in most previous studies, psychological issues of college students have been associated with restraints in seeking medical services [31–33]. It should be considered that the health examination process of the FSHS may provide the students a low threshold gateway to mental health services.

In the eHQ, the students were able to indicate their willingness to discuss with a health care professional which according to the present results was negatively associated with health check non-attendance. It is possible that these students had health concerns and suitable timing of the eHQ offered them an easy access to health services, explaining the finding. Previously described facilitators of health check attendance as feeling responsible for one's health, finding health important and believing to be able to influence one's own health may explain the finding as well [34].

Despite the large number of variables examined, health- or health habit-related reasons did not seem to be associated with the health check non-attendance to a great extent in the university student population. In previous studies, conducted in non-student populations, the reasons for not attending general health checks have often been non-health-related, including lack of awareness, long distances or other difficulties with access to the health care, and time constraints [4, 8, 9]. It has been stated that young people are often unwilling or unable to obtain needed health services, indicating barriers related to the availability, accessibility and acceptability of health services [35]. We expect factors such as these to partially explain the health check non-attendance of university students, however they were not in a scope of this study and should be a subject for further research.

Strengths and limitations

The greatest strengths of this study were the wide variety of factors studied, the real-life setting and using register data on a national cohort of university entrants. This was the first study to address the reasons for health check non-attendance in a student health care setting. The reasons for the lack of previous research can be diverse. In general, health checks are understudied [2] which could be due to the strong tradition they have in preventive health care. Further, the global concern about students' mental health [28] might have directed the research resources to psychosocial factors.

There are inherent limitations in the health examination process of the FSHS, and the real-life design of this study. The eHQ was developed for practical purposes and was validated accordingly, and not to the degree of scientific rigor [10]. The eHQ data are self-reported data and are therefore susceptible to bias [36]. As the response rate to the eHQ was fairly low (55%), almost half of university entrants did not have their needs for a health check screened.

Conclusions

The results suggest that providing health checks may serve as a way of reaching students with health concerns, which could translate into opportunities to incur health benefits of general health checks in student health care. However, motivating males and smokers to attend general health checks continue to be a challenge also in a university student population. That low engagement with studies associates with health check non-attendance points to clear need to improve collaboration between universities and student health care.

Declarations

Ethics approval and consent to participate

The study was conducted under the guidelines of the Finnish National Board on Research Integrity. The study has been ethically reviewed by the Ethics Committee of the Tampere Region (review 2/2017). The review was affirmative. Approval was also granted from the Finnish National Institute of Health and Welfare, which authorises the research use of confidential data in Finland (Dnro THL/1364/5.05.00/2017). The study received permission from the FSHS to conduct research.

This study used pseudonymized data from the registers of the Finnish Student Health Service. In the data, individuals could not be identified, thus informed consent could not be obtained. The exception to informing obligations is based on The General Data Protection Regulation article 62. The lawful base for processing personal data in this study was public interest as stated in Tampere University Information Security Policy. A risk assessment and data protection plan has been delivered to the Finnish office of the data protection ombudsman.

Authors' contributions

NS designed the study. NS and SP collected the data. NS processed and analysed the data and wrote the manuscript. SP, KK and MK significantly contributed to the design of the study and revised the manuscript. RA significantly contributed to the statistical design and revised the manuscript. All authors have read and approved the final manuscript.

Acknowledgements

We want to thank the Finnish Student Health Service and our funders for enabling this study. Further, we want to express our gratitude to public health nurse Ritva-Liisa Hannula and development manager Elina Heilala of the FSHS for offering their valuable support.
