ABSTRACT

Introduction Evidence-based preoperative, intraoperative and postoperative glycemic management may reduce poor surgical outcomes. Previous studies suggest that quality gaps in perioperative glycemic management may be common.

Research design and methods This retrospective cohort study used administrative health and laboratory data from a single center to estimate quality gaps in perioperative glycemic management in patients with and without diabetes between April 2019 and March 2020. We examined the proportion of patients with preoperative hemoglobin A1c (HbA1c) measurement, postoperative point-of-care testing (POCT) for glucose, hyperglycemia, and basal bolus insulin regimens. We compared the median length of stay (LOS) in patients with and without postoperative hyperglycemia, adjusted for age and sex.

Results There were 6576 patients in our cohort; 1165 (17.8%) had diabetes. Most patients with diabetes had an HbA1c measured prior to surgery (n=697, 59.8%). Postoperatively, 16.9% of patients with diabetes had no POCT monitoring (n=197) and 65.7% had hyperglycemia (n=636). Only 35.9% of patients who received insulin had a basal bolus insulin regimen (n=229). Patients with diabetes who had postoperative hyperglycemia had a longer median LOS compared with those who did not have postoperative hyperglycemia (8.4 days (95% CI 7.5 to 9.4) and 6.7 days (95% CI 6.3 to 7.1), respectively). In patients without diabetes, median LOS was 7.4 days (95% CI 4.4 to 10.4) for those with hyperglycemia and 5.2 days (95% CI 5.1 to 5.4) for those with in-target glucose.

Conclusions Quality gaps in perioperative glycemic management include measurement of blood glucose after surgery and treatment of postoperative hyperglycemia. These gaps may contribute to longer LOS.

INTRODUCTION

Patients with postoperative hyperglycemia have worse outcomes compared with patients with euglycemia, including increased length of stay (LOS), greater need for intensive care, more frequent hospital readmission, and more frequent infections.^{1–5} Patients with postoperative glucose measurements even 1.0 mmol/L above target have an absolute

Significance of this study

What is already known about this subject?

▶ Postoperative hyperglycemia is associated with worse outcomes for patients with and without diabetes.

What are the new findings?

- ▶ We identified important quality gaps in perioperative glycemic management at our center.
- ▶ Forty percent of patients were not screened for risk of postoperative hyperglycemia before surgery.
- ▶ Seventeen percent of patients with known diabetes had no measurement of blood glucose after surgery and two-thirds had hyperglycemia.
- ▶ Patients with and without diabetes who had hyperglycemia had a longer length of stay than patients without hyperglycemia.

How might these results change the focus of research or clinical practice?

▶ Altogether, these results highlight the need for theory-informed knowledge translation strategies to improve perioperative glycemic management.

30-day mortality risk that is 0.6% higher than patients who are within target.⁶ In addition, patients with postoperative hyperglycemia have 6% more infections than patients with euglycemia.^{6,7}

While patients with diabetes are at greatest risk of postoperative hyperglycemia, an additional 5%–10% of patients without diabetes also experience postoperative hyperglycemia⁸ and an estimated 10% of patients have unrecognized diabetes.² Since diabetes affects 20%–30% of surgical patients,⁹ a conservative estimate is that 25%–35% of surgical patients are at risk of postoperative hyperglycemia.

Evidence-based and guideline-informed perioperative glycemic management has reduced LOS and surgical site infections;^{10–12} however, implementation of best practices

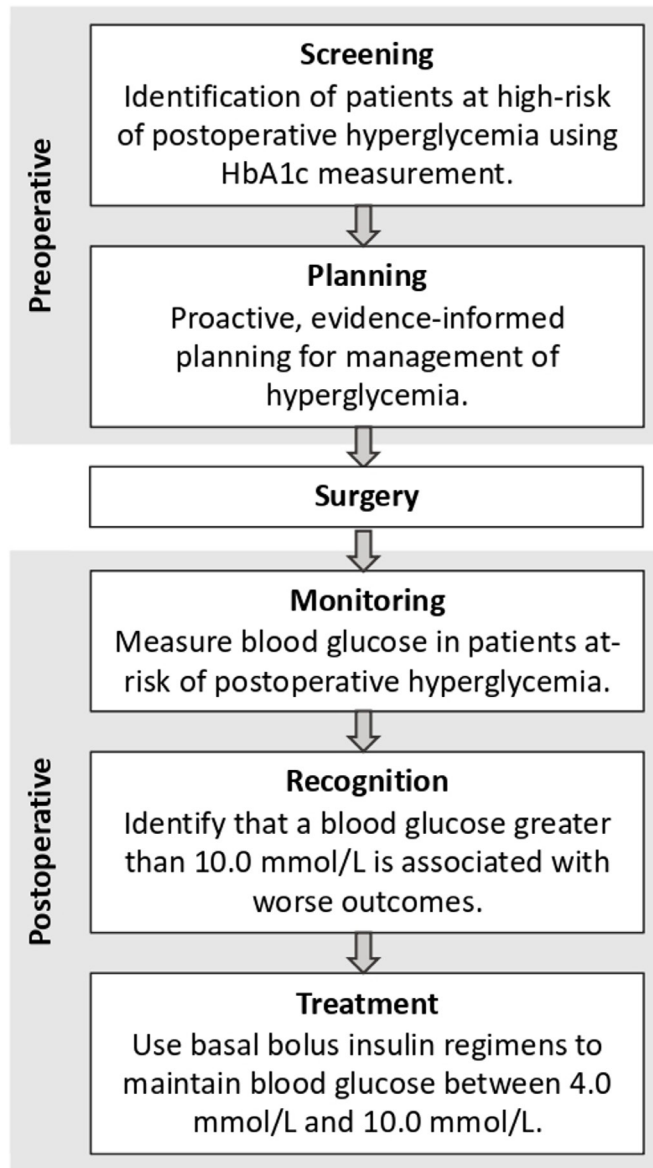

Figure 1 Process map detailing perioperative glycemic management. HbA1c, hemoglobin A1c.

for glycemic management is challenging.¹³ Implementation in the perioperative period is further complicated by the need to coordinate clinical care between multiple medical specialists (eg, surgeons, internal medicine, anesthesia) and settings (eg, the preoperative outpatient surgical appointment, preoperative outpatient internal medicine appointment, and the inpatient surgical hospitalization). Successful perioperative glycemic pathways are multidisciplinary and require significant stakeholder engagement.^{10 11}

We have previously reported a framework for understanding and evaluating perioperative glycemic management (figure 1).¹⁴ This framework requires: (1) preoperative screening for risk of postoperative hyperglycemia based on hemoglobin A1c (HbA1c) results; (2) proactive planning for patients at risk of postoperative hyperglycemia; (3) postoperative monitoring for

hyperglycemia using capillary glucose point-of-care testing (POCT); (4) recognition of postoperative hyperglycemia; and (5) appropriate treatment of postoperative hyperglycemia.

Previous quality improvement work by our study team and other groups suggests that there are important quality gaps in perioperative management of hyperglycemia.^{15–17} In the UK, nearly 50% of patients with diabetes undergoing surgery did not have any blood glucose measurements intraoperatively and 14% had no measurements in the immediate recovery room.¹⁵ In our center, fewer than half of patients with diabetes who were seen by an internal medicine physician before surgery had recommendations for postoperative glycemic management.¹⁶ Further, we found that surgical team members reported low perceived skills for recognizing and managing postoperative hyperglycemia.¹⁶ Therefore, the objective of this current study was to evaluate current screening, monitoring, and treatment for patients with and without diabetes in our setting to identify potential quality gaps. Our secondary objective was to estimate the association between postoperative hyperglycemia and LOS.

RESEARCH DESIGN AND METHODS

Study design

This retrospective cohort study used electronic health record (EHR) data to measure process, outcome, and balancing measures tied to a previously described framework for perioperative glycemic management¹⁴ to assess the quality of perioperative diabetes management in a single hospital system.¹⁸ This manuscript is reported according to the Reporting of Studies Conducted Using Observational Routinely Collected Health Data extension¹⁹ of the Strengthening the Reporting of Observational Studies in Epidemiology guidelines²⁰ and the Strengthening the Reporting of Cohort Studies in Surgery guideline.²¹

Setting

The cohort was derived of patients undergoing non-cardiac surgery at a quaternary acute care academic hospital in Canada with a catchment area over more than 2 million people. Endocrinology and internal medicine consultation services are available 24 hours/day, every day. This hospital uses an EHR (Sunrise Clinical Manager; Allscripts, Richmond, British Columbia, Canada) that houses all admission, LOS, point-of-care capillary glucose data, and inpatient laboratory results. All outpatient laboratory results that are performed in our province are contained in a separate information system (Netcare; Alberta Health and Wellness) which is integrated into the inpatient EHR. Comorbidity data for each hospitalization are recorded using the Tenth Revision of International Statistical Classification of Diseases and Related Health Problems codes that have been modified for Canadian use, found in the discharge abstract database (DAD). Procedure codes based on the Canadian Classification of

Health Interventions are housed in Picis patient management software (Wakefield, Massachusetts). Data from the EHR were linked to the DAD and the provincial outpatient laboratory database. Personal healthcare numbers were used to create person-level, deterministic linkages across the various databases accessed. Over 99% of Albertans are enrolled in free comprehensive health insurance and health services are publicly administered. Hence, outpatient data including labs are nearly completely captured for use in health studies such as ours.

Population

We included adults 18 years and older who underwent non-cardiac surgery at our hospital and were admitted for more than 24 hours after surgery between 1 April 2019 and 30 March 2020. Patients were pragmatically categorized as having diabetes if they had a diagnosis of diabetes in the DAD^{22 23} or an outpatient HbA1c greater than 6.5% (48 mmol/mol) in the year before surgery or during the surgical admission.²⁴ Patients were considered to not have diabetes if they had an HbA1c in the year before surgery or during the surgical admission that was less than 6.4% (46 mmol/mol) and no diagnosis of diabetes in the DAD.²⁴ Patients had an unknown diabetes status if they had no diagnosis of diabetes in the DAD and no HbA1c in the year before surgery or during the surgical admission. The exposure of interest in this study for the analysis of LOS was diabetes diagnosis.

Surgical urgency was determined by the surgeon and extracted from the request for surgical booking. Emergent surgeries are scheduled within 24 hours of the request, urgent surgeries are scheduled between 3 days and 6 weeks from the request, and elective surgeries are booked at any available time from the request.

Outcomes

Outcomes were defined using the perioperative glycemic process map developed with input from endocrinologists, perioperative internists, surgeons, data analysts, and quality improvement experts (figure 1).¹⁴ Measures are reported separately for patients with and without diabetes, and are stratified into screening measures, perioperative monitoring measures, perioperative glycemic outcome measures, and balancing measures. All measures are reported for the first 24 hours after surgery, which is based on previous work that suggests this is the most critical time period for development of adverse postoperative complications due to hyperglycemia.⁶ We defined in-target point-of-care capillary glucose measurement using the Diabetes Canada target as between 4.0 and 10.0 mmol/L.²⁵ We measured the proportion of high-risk patients who underwent preoperative HbA1c measurement within the year prior to surgery or during the surgical admission. Monitoring for postoperative hyperglycemia was based on the number of POCT measurements in the first 24 hours after surgery. There are no major society guideline recommendations on the optimal number

of POCT measurements after surgery,²⁶ but our institutional policies recommend four times per day for patients using insulin or with diabetes and fasting.²⁷

Outcome measures included the proportion of POCT per patient that were in target, and number of patients with moderate (one or more POCT results between 14.0 and 17.9 mmol/L) or severe hyperglycemia (one or more POCT results >18.0 mmol/L), considering only patients who had at least one POCT measurement. The balancing measure was the number of patients who experienced a hypoglycemic episode (one or more POCT results <4.0 mmol/L).

Patients were categorized as having received a sliding scale insulin regimen (also called variable dose subcutaneous insulin regimen or correction-only dose insulin) if they received correction dose insulin alone without scheduled mealtime (if not nil per os (NPO)) or basal insulin for more than 65% of their inpatient stay. Patients were considered to have received a basal bolus insulin regimen if they received an ultra-long-acting, long-acting, or intermediate-acting insulin formulation and a scheduled mealtime insulin (if eating) dose for more than 65% of their inpatient stay. Intravenous insulin is only used during metabolic decompensation or in critical care units in our hospital and is not routinely used for the perioperative setting.²⁶ Length of hospital stay in days was extracted from the EHR.

Statistical analysis

Statistical analyses were performed using Stata software V.16.0 (StataCorp), using two-sided statistical significance ($p < 0.05$). Baseline characteristics are summarized for the overall cohort and for patients with and without diabetes and patients with no HbA1c measurement in the 1 year before surgery. We report counts and percentages for categorical variables and medians with IQRs for non-parametric continuous variables. For our exploratory outcome of LOS, we used quantile regression to estimate age and sex-adjusted LOS (and accompanying 95% CIs). We used a four-level categorical exposure in this analysis to compare patients with and without diabetes who had and did not have postoperative hyperglycemia: (1) diabetes and hyperglycemia, (2) diabetes and no hyperglycemia, (3) no diabetes and hyperglycemia, and (4) no diabetes and no hyperglycemia.

RESULTS

There were 6576 patients who met the inclusion criteria during the study period. The median age was 64 years (IQR 55–72 years) and 55.8% were female ($n=3671$). The median postoperative LOS was 5 days (IQR 2–11 days) and most surgeries were categorized as urgent ($n=3011$, 45.8%) (table 1). Less than half of all patients had a recent HbA1c measurement (41.8%, $n=2746$), including 59.8% of patients with diabetes ($n=697$).

Table 1 Cohort characteristics by diabetes status

	Total cohort	Diabetes	No diabetes*	No HbA1c measurement

*HbA1c <6.5% and no diagnosis of diabetes in the discharge abstract database (DAD).
HbA1c, hemoglobin A1c.

Patients with diabetes

Of the entire cohort, 1165 (17.8%) had diabetes. The median preoperative HbA1c for these patients was 7.0% (53 mmol/mol; IQR 6.5%–7.9%) (table 1). After surgery, 16.9% of these patients with diabetes had no

POCT measurements (n=197) (table 2). Of patients with diabetes who had at least one POCT measurement after surgery, 65.7% had hyperglycemia (n=636) and 16.9% and 5.1% experienced moderate and severe hyperglycemia, respectively, in the first 24 hours after surgery.

Capillary glucose between 4.0 and 10.0 mmol/L is considered within target; moderate hyperglycemia is 14.0–17.9 mmol/L; severe hyperglycemia is ≥ 18.0 mmol/L.
POCT, point-of-care testing.

Nearly one in five patients with diabetes had no POCT measurements that were in target (4.0–10.0 mmol/L). Only 72.0% of patients with diabetes who had hyperglycemia received insulin during their admission and nearly 11% of patients with severe hyperglycemia did not receive insulin. Only 35.9% of patients with diabetes who received insulin in hospital received treatment with a basal bolus insulin regimen (n=229) and 64.1% received a sliding scale-only regimen (n=409). The proportion of patients with diabetes who received at least one POCT after surgery and who had postoperative hyperglycemia varied by surgical service (table 3).

Patients without diabetes

There were 2049 patients without diabetes, as defined by HbA1c less than 6.4%,²⁴ and no diagnosis of diabetes recorded in the DAD (31.2%). Most of these patients had no monitoring for hyperglycemia after surgery (table 2). Of patients with at least one POCT measurement after surgery, hyperglycemia occurred in 18.3% (n=38/208) and most was mild (POCT 10.0–13.9 mmol/L). Less than half of patients with hyperglycemia received insulin and sliding scale-only regimens were more common than basal bolus insulin regimens.

Patients with unknown diabetes status

Nearly half of all patients had an unknown diabetes status (n=3362, 51.1%) (table 2). Most of these patients had no

POCT measurements in the first 24 hours after surgery (n=3115, 92.7%). Of the patients with an unknown diabetes status who had at least one POCT measurement, 27.9% had hyperglycemia (n=69/247), and 2.1% and 1.2% had moderate and severe hyperglycemia, respectively. Sliding scale-only insulin regimens were again more common than basal bolus insulin regimens.

Hospital LOS

Patients with diabetes who had postoperative hyperglycemia had a higher median-adjusted LOS of 8.4 days (95% CI 7.5 to 9.4) when compared with patients with diabetes who did not have postoperative hyperglycemia with a median LOS of 6.7 days (95% CI 6.3 to 7.1). In patients without diabetes, the median LOS for patients with postoperative hyperglycemia was 7.4 days (95% CI 4.4 to 10.4) and for patients without postoperative hyperglycemia it was 5.2 days (95% CI 5.1 to 5.4) (table 4).

CONCLUSIONS

This large retrospective cohort study identified important quality gaps in perioperative glycemic management and reports an exploratory association of postoperative hyperglycemia with increased LOS in patients with and without postoperative hyperglycemia. In particular, we report inadequate monitoring for and treatment of postoperative hyperglycemia in patients with diabetes.

Table 4 Median-adjusted* length of stay (95% CI) for patients with and without diabetes who had postoperative hyperglycemia

	Postoperative hyperglycemia (>10.0 mmol/L)	No postoperative hyperglycemia (<10.0 mmol/L)
Diabetes	8.4 (7.5–9.4)	6.7 (6.3–7.1)
No diabetes	7.4 (4.4–10.4)	5.2 (5.1–5.4)

*Adjusted for sex and age at the time of the procedure.

Postoperative hyperglycemia was common; the proportion of patients with postoperative hyperglycemia ranged from 1 in 6 for patients without diabetes to 2 in 3 for patients with known diabetes. In our setting, patients with hyperglycemia had an estimated LOS that was 1.7 days longer for patients with diabetes and 2.2 days for patients without known diabetes. Altogether, these data suggest important quality gaps in perioperative glycemic management from screening patients for diabetes to appropriate treatment of patients with hyperglycemia.

In our study, 42% of patients had no recent HbA1c measurement. This is similar to other settings, where about half of patients with diabetes underwent preoperative HbA1c measurement.^{15 28} While Diabetes Canada does not recommend preoperative screening for diabetes, expert panels and other major society guidelines suggest universal HbA1c measurement for patients with diabetes undergoing surgery.^{17 29 30} Studies with universal preoperative measurement of HbA1c for all patients undergoing surgery estimate that 4%–11% of patients have unrecognized diabetes.^{2 31 32} In addition, preoperative HbA1c is a strong predictor of postoperative hyperglycemia, even in patients without diabetes.⁶ A large observational study by Jones *et al* found that patients with known diabetes were more likely to undergo monitoring for postoperative hyperglycemia and were more likely to receive appropriate treatment for hyperglycemia than patients with postoperative hyperglycemia who did not have diabetes.² Similarly, a UK-based study found that intraoperative and postoperative glucose testing was more commonly performed for patients with diabetes when their diagnosis of diabetes was included on the surgical safety checklist.¹⁵ Altogether, this evidence suggests that preoperatively identifying patients with abnormal HbA1c may improve quality of care. At minimum, surgical patients who qualify for diabetes screening based on risk factors such as age, family history, or obesity should undergo HbA1c measurement.³³

While most major society guidelines do not comment on the optimal number of POCT after surgery for patients with diabetes,^{25 30} previous evidence suggests that patients who undergo increased POCT have improved outcomes, including fewer hospital readmissions within 30 days.² We report that 17% of patients with diabetes had no POCT measurement in the first 24 hours after surgery. Due to these low rates of postoperative POCT in patients

with diabetes, we cannot estimate the true burden of hyperglycemia in our setting; however, at minimum, 55% of patients with diabetes in our study had at least one episode of hyperglycemia. This is lower than other centers, which found that about 90% of postoperative patients with diabetes had hyperglycemia.^{34 35}

Glucose measurement was infrequently performed in patients without known diabetes, and thus we cannot reliably estimate the proportion of these patients who had hyperglycemia. There were 28% of patients with unknown diabetes status and 18% of patients without diabetes who had postoperative hyperglycemia; however, this may be overestimated due to indication bias. Studies that performed POCT in all surgical patients identified postoperative hyperglycemia in 20%^{15 35} to 60%^{32 36 37} of patients without known diabetes. Even a single episode of hyperglycemia has been associated with increased LOS, twofold increase in reoperation, and 10-fold increase in 30-day mortality in patients without diabetes.³² Without adequate testing, many episodes of hyperglycemia are likely unrecognized and therefore untreated in our setting. Given prevalence of postoperative hyperglycemia in patients without diabetes in our study and in other settings, the utility of POCT in patients without diabetes should be an area of future study.

More than a quarter of patients with diabetes and more than half of patients without known diabetes who had hyperglycemia did not receive insulin, including 10% of patients with diabetes who had blood glucose greater than 18.0 mmol/L. In addition, we found that most patients with hyperglycemia were treated with sliding scale-only regimens rather than the recommended basal bolus insulin regimens, advocated by Diabetes Canada based on high-quality evidence.²⁵ This is considerably greater than the 24% of patients with diabetes who had ‘inappropriate’ postoperative management of diabetes reported in other studies.¹⁵ The landmark RABBIT-2 trial (Randomized Study of Basal-Bolus Insulin Therapy in the Inpatient Management of Patients With Type 2 Diabetes 2 trial) randomized patients undergoing surgery to sliding scale insulin or basal bolus insulin regimens, and found that patients who were prescribed basal bolus regimens had improved glycemic control and fewer in-hospital complications.³⁸ Barriers to use of basal bolus insulin regimens have been previously identified and include fears of hypoglycemia, lack of skills to prescribe these regimens by surgical team members, and clinical inertia.^{13 16} Evidence-informed knowledge translation strategies to increase use of basal bolus insulin regimens for postoperative patients with hyperglycemia are needed.

Altogether, our results demonstrate a quality gap for patients with and without diabetes undergoing surgery that is associated with worse clinical outcomes, including hyperglycemia and longer LOS. Perioperative glycemic care pathways that protocolize preoperative screening for diabetes, postoperative measurement of glucose, and evidence-based treatment of postoperative hyperglycemia demonstrate reduced postoperative

hyperglycemia.^{10 11 29} Further, implementation of these pathways may also improve clinical outcomes, in particular surgical site infections.^{10 11 29} With the burden of postoperative hyperglycemia and its association with worse clinical outcomes, multidisciplinary perioperative teams should consider implementation of standard POCT measurement protocols for patients with diabetes. Implementation of perioperative glycemic management pathways should be guided by theory and evidence to increase uptake and sustainability.

Our study has important limitations. Due to the low proportion of patients who underwent POCT for blood glucose, estimates of the prevalence of postoperative hyperglycemia and of the association between postoperative hyperglycemia and patient outcomes, including LOS, are limited. Therefore, the association between postoperative hyperglycemia in patients with and without diabetes and longer LOS should be considered exploratory. Despite this limitation, increased LOS for surgical patients with diabetes has been reported in multiple observational studies.^{1 3} In addition, while we included a variety of surgical disciplines, our result is from a single hospital and the generalizability of these results to other centers is unknown; however, data from other studies suggest that similar quality gaps for surgical patients with diabetes are common.¹⁵

This large, retrospective study of hospitalized surgical patients found that low proportions of patients with and without diabetes undergo preoperative HbA1c measurement and postoperative monitoring for hyperglycemia. The proportion of patients with postoperative hyperglycemia was high, and though this estimate of hyperglycemia is likely confounded by the indication for blood glucose measurement, it highlights a gap to optimize in this population. Patients with hyperglycemia more commonly received sliding scale insulin regimens rather than recommended basal bolus insulin regimens. Further, we found that patients with postoperative hyperglycemia had a longer LOS, regardless of a diagnosis of diabetes. Additional research is needed on the utility of preoperative HbA1c measurement and postoperative POCT for patients without diabetes. Overall, these results suggest knowledge translation and quality improvement work is needed to realize and reduce the burden of postoperative hyperglycemia in patients with and without diabetes undergoing surgery.
