Background: Stroke and myocardial infarction (MI) are associated with each other, as demonstrated in observational studies. However, it is unclear whether this relationship is causal, and the purpose of this study was to explore the bidirectional causality between stroke and MI.

Methods: Causality between stroke and MI was assessed using two-sample Mendelian randomization (MR). All genetic instruments related to stroke (40,585 cases; 406,111 controls) and MI (43,676 cases; 128,199 controls) were derived from large published genome-wide association study. The MR analysis was calculated with inverse-variance weighting, MR-Egger, weighted mode, weighted median, and simple mode methods, and sensitivity analyses are used to detect the heterogeneity or pleiotropy.

Results: Genetically predicted large-artery stroke (LAS) was causally related to higher odds of MI (odds ratio [OR] = 1.13, 95% confidence interval [CI]: 1.06–1.20, $p = 1.0 \times 10^{-4}$), and the causal effect of LAS on MI was significantly weakened (OR = 1.09, 95% CI: 1.02–1.17, $p = 0.017$) after excluding the multipotent single-nucleotide polymorphisms (SNPs). MI phenotypes were genetically correlated with all ischemic strokes (OR = 1.15, 95% CI: 1.03–1.28, $p = 0.013$) and LAS (OR = 1.39, 95% CI: 1.14–1.71, $p = 0.001$); but a causal effect of MI on all ischemic strokes (OR = 1.00, 95% CI: 0.95–1.28, $p = 0.219$) and LAS (OR = 1.26, 95% CI: 0.93–1.69, $p = 0.130$) was not observed after excluding the multipotent SNPs.

Conclusion: This MR analysis provides evidence to support the causal effect of LAS subtype on MI, and some factors act as confounding factors whereas others may act as mediators.

Keywords: causal inference, single-nucleotide polymorphism, genome-wide association study, epidemiologic methods, large-artery stroke

Introduction

Stroke and myocardial infarction (MI) are major clinical and public health problems. Both have a significant global impact; stroke leads to disability and mortality,¹ and MI causes more than 7 million deaths worldwide annually.²

Observational studies confirmed that ischemic stroke and MI are interrelated.³ Patients with acute ischemic stroke have a high risk of MI, and the 5-year risk of MI after stroke is 8.6%.⁴ Stroke causes autonomic dysfunction and systemic inflammation, and these dysregulation promote arrhythmia, microvascular dysfunction, coronary ischemia and myocardial necrosis.^{5,6} It has been reported that stroke is a serious complication after MI,⁷ with annual an incidence rate of up to 4%.⁸ Left ventricle akinesia and/or dyskinesia after MI possibly increase the risk of mural thrombosis and cause stroke or peripheral thromboembolism.⁹ However, observational research has some potential biases, which may be caused by confounding factors or reverse causality. These biases cause the inability to form stable causal inferences in observational research when

interpreting the results,¹⁰ so the causality behind these associations remains largely unclear. Thus, exploring new methods to prove the causal link between stroke and MI is important.

As a new epidemiological method, Mendelian randomization (MR) provides a stronger causal inference between exposure and disease risk.¹¹ MR analysis detects the causal relationship between exposure factors and outcomes by using genetic variation as instrumental variables (IVs).¹² MR can compensate for the shortcomings of traditional epidemiological studies that are affected by confounding factors and reverse causality.¹³ Recently, genome-wide association studies (GWASs) have been extensively performed and provides data resources for MR.¹⁴ The purpose of this study was to comprehensively explore the causality between ischemic stroke and MI using a two-sample bidirectional MR analysis.

Materials and Methods

Study Design

A two-sample MR study was performed to explore the potential causal relationship between ischemic stroke and

its subtypes and MI. MR studies are based on three main assumptions (Figure 1A).¹⁵ IVs are related to exposure with genome-wide significance; the IVs are not related to any of the confounders associated with exposure or outcome; and the IVs influence outcome only through exposure. This study used a two-sample bidirectional MR method, and the design is shown in Figure 1B. In addition, we used the Strengthening the Reporting of Observational Studies in Epidemiology– Mendelian randomization (STROBE-MR)¹⁶ guidelines for reporting this study.

Data Sources

The diagnosis of ischemic stroke complied with the guidelines for early management of patients with acute ischemic stroke,¹⁷ and the diagnosis of MI in this study was based on the definition of American Heart Association (AHA) and American College of Cardiology (ACC).¹⁸ The data of ischemic stroke and its subtypes were acquired from GWASs of up to 446,696 individuals (40,585 cases; 406,111 controls) of European ancestry, conducted by the

MEGASTROKE consortium.¹⁹ Ischemic stroke was divided into three subtypes: large-artery stroke (LAS), cardioembolic stroke (CES), and small vessel stroke (SVS). Data on MI were acquired from a large GWAS meta-analysis with 171,875 subjects (43,676 cases; 128,199 controls) of European ancestry, conducted by the CARDIoGRAMplusC4D consortium.²⁰ These original GWASs obtained ethical approval and informed consent from all participants.

Single-Nucleotide Polymorphism (SNP) Selection

All ischemic stroke and its subtypes were used as the exposure, and nine SNPs related to all ischemic stroke at genome-wide significance ($p < 5 \times 10^{-8}$) were selected as genetic instruments.¹⁹ By testing linkage disequilibrium ($r^2 > 0.01$, $\text{kb} < 5000$),²¹ no SNP was excluded. To assess whether these SNPs were associated with confounding or risk factors for disease outcome, every SNP was searched in PhenoScanner^{22,23} (<http://www.phenoscanter.medschl.cam.ac.uk/>) to exclude potential pleiotropy. Three SNPs (rs2634074, rs2107595, rs3184504) were associated with hypertension, type II diabetes, atrial fibrillation, and coronary heart disease and were excluded. Subsequently, we calculated the F-statistic of these SNPs (ranging from 74.0 to 150.6), indicating they were strong instruments for this MR study.²⁴ The SNPs associated with ischemic stroke subtypes (LAS, CES, and SVS) were screened in the same way. Notably, there was no significant SNP ($p < 5.0 \times 10^{-8}$) in SVS; thus, we did not perform the analysis for SVS.

When MI was used as the exposure, 26 SNPs related to MI at genome-wide significance ($p < 5 \times 10^{-8}$) in the published GWAS²⁰ were used as genetic instruments. One SNP (rs10176176) was excluded by testing linkage disequilibrium. Subsequently, 25 SNPs were detected in PhenoScanner, and 13 SNPs (rs7528419, rs72689147, rs2327426, rs10947786, rs1510226, rs10455872, rs11556924, rs532436, rs653178, rs2681472, rs7173743, rs41290120, rs113113862) were associated with body mass index, current smoking, hypertension, type II diabetes, atrial fibrillation, low/high-density lipoprotein cholesterol or total cholesterol, and were excluded. The F-statistic of the selected IVs ranged from 11.0 to 124.4, avoiding weak instrument bias.

Statistical Analyses

Statistical analyses of all data were performed using R (version 4.0.5) and a two-sample MR package.²⁵ The

main analysis was carried out by the random effects inverse-variance weighting (IVW) method,²⁵ which provides consistent and efficient estimates when all genetic variants are valid. The weight of IVW comes from the reciprocal of the estimated variance of the Wald ratio of each SNP, and its weight represents the estimated accuracy of the Wald ratio of each SNP. The MR-Egger, weighted median, simple mode, and weighted mode regression methods were performed as complementary analyses. The MR-Egger method can provide robust estimates for situations that may violate standard IV assumptions due to directional pleiotropy.²⁶ The weighted median method can provide robust estimates even if up to 50% of the information comes from ineffective IVs.²⁷ In sensitivity analyses, we used the heterogeneity, pleiotropy, and leave-one-out tests. The heterogeneity test assessed the difference between each genetic variant. The MR-Egger intercept was used to assess horizontal pleiotropy, and horizontal pleiotropy, which was determined to exist if there was a large gap between the intercept term and zero. The leave-one-out analysis was conducted to test the robustness of the results by sequentially excluding one SNP at a time. The associations between genetically predicted exposure and outcome were presented as odds ratios (ORs) and 95% confidence intervals (CIs). An observed two-sided p values < 0.05 were considered as significant evidence for a causal association, and a Bonferroni correction (p -value after correction = $0.05/\text{number of exposures/the number of outcomes}$) was used for multiple comparisons.

Results

We used two-sample bidirectional MR to analyze the causal relationship between MI and ischemic stroke. Genetically predicted stroke had a causal effect on MI but the causal effect of MI on stroke and its subtypes was not observed (Figure 1B). The detailed results were as follows.

Effect of All Ischemic Stroke and Its Subtypes on the Risk of Myocardial Infarction

All ischemic stroke and each of its subtypes were used as the exposure. There were nine available SNPs for all ischemic stroke, four SNPs for CES, four SNPs for LAS, and no available SNPs for SVS. The characteristics of these SNPs are shown in [Online Supplemental Table 1](#). The main results

of the MR analysis of the causal effect of stroke on MI are presented in Figure 2. The results showed a causal effect of all ischemic stroke on MI (odds ratio [OR] = 1.31, 95% confidence interval [CI]: 1.05–1.63, $p = 0.016$), and LAS on MI (OR = 1.13, 95% CI: 1.06–1.20, $p = 1.0 \times 10^{-4}$), but CES had no causal effect on MI (OR = 1.00, 95% CI: 0.94–1.06, $p = 0.942$). The sensitivity analysis indicated heterogeneities among individual SNPs of all ischemic stroke on MI ($p = 2.95 \times 10^{-5}$), but there were no heterogeneities of LAS on MI ($p = 0.355$) and CES on MI ($p = 0.939$). The MR-Egger analysis showed that there was no horizontal pleiotropic effect: all ischemic stroke on MI (intercept = -0.013 , $p = 0.844$), LAS on MI (intercept = -0.017 , $p = 0.424$), and CES on MI (intercept = 0.002 , $p = 0.894$). By leave-one-out analysis, the results of all ischemic stroke (Figure 3A) and LAS (Figure 3B) on MI were robust and not significantly driven by any single SNP.

In addition, we analyzed the remaining six SNPs to observe the causal effect of all ischemic stroke on MI (Figure 2). The results demonstrated that the causal effect of all ischemic stroke on MI was significantly weakened

using six SNPs (OR = 1.15, 95% CI: 1.00–1.33, $p = 0.046$), which excluded SNPs associated with confounding factors. In the sensitivity analyses, this study did not find any heterogeneity ($p = 0.598$) or directional pleiotropy (intercept = 0.015 , $p = 0.809$) for six SNPs. The effect of all ischemic stroke on MI was not substantially driven by any single SNP by leave-one-out analysis (Figure 3C). Regarding the effect of LAS on MI, the results (Figure 2) indicated the causal association between LAS and MI was significant with 3 SNPs (OR = 1.09, 95% CI: 1.02–1.17, $p = 0.017$), and this causal relationship remained significant after Bonferroni correction (Bonferroni-corrected p -value: 0.017). The scatter plot in Figure 4 shows that the risk of MI increases as the genetically odds of LAS increase genetically. Moreover, sensitivity analyses confirmed there was no heterogeneity ($p = 0.771$) or pleiotropy (intercept = 0.009 , $p = 0.681$) for LAS on MI using three SNPs. The leave-one-out analysis (Figure 3D) demonstrated that the causal effect of LAS on MI is robust after eliminating confounding factors.

Effect of Myocardial Infarction on Risk of All Ischemic Stroke and Its Subtypes

When MI was used as the exposure, 25 eligible SNPs were obtained, and they are shown in [Online Supplemental Table 2](#). The MR analysis of the causal effect of MI on ischemic stroke is presented in [Figure 5A](#). The results revealed that the genetic prediction of MI was related to an increased risk of all ischemic stroke (OR = 1.15, 95% CI: 1.03–1.28, $p = 0.014$) and LAS (OR = 1.39, 95% CI: 1.14–1.71, $p = 0.001$). The causal effect of MI on CES (OR = 1.11, 95% CI: 0.99–1.25, $p = 0.086$) and SVS (OR = 1.03, 95% CI: 0.85–1.25, $p = 0.742$) was not significant. In the sensitivity analysis, the results indicated strong heterogeneities for all ischemic stroke ($p = 5.21 \times 10^{-16}$), LAS ($p = 1.17 \times 10^{-6}$), and SVS ($p = 1.92 \times 10^{-6}$), but not for CES ($p = 0.032$). There was no directional pleiotropy for the relationship between the SNPs and risk of all ischemic stroke (intercept = 0.004, $p = 0.748$), LAS (intercept = -0.022, $p = 0.379$), CES (intercept = 0.001, $p = 0.924$), and SVS (intercept = 0.025, $p = 0.277$) in MR-Egger regression. The causal effect of MI on all ischemic stroke ([Figure 3E](#)) and LAS ([Figure 3F](#)) was not driven by any single SNP as indicated by leave-one-out analysis. After excluding the multipotent SNPs, the analysis results of the remaining 12 SNPs showed that MI had no causal effect on all ischemic stroke (OR = 1.10, 95% CI: 0.95–1.28, $p = 0.219$), on LAS (OR = 1.26, 95% CI: 0.93–1.69,

$p = 0.130$), on CES (OR = 1.11, 95% CI: 0.97–1.27, $p = 0.115$) and on SVS (OR = 1.02, 95% CI: 0.77–1.35, $p = 0.913$) ([Figure 5B](#)).

Discussion

In this study, the primary two-sample MR analysis provided evidence that genetically increasing odds of LAS subtype has a causal relationship with increased risk of MI, whereas the causal effect of MI on stroke and its subtypes was not detected. Furthermore, we used different statistical models and instruments to demonstrate that these results are robust.

Patients with transient ischemic attack or stroke have a high risk of MI according to a meta-analysis,²⁸ which included 39 studies with 65,996 patients. Through a multicenter stroke registry in Korea, two studies^{29,30} revealed that the 1-year and 5-year cumulative incidence rates of MI after acute ischemic stroke were 0.5% and 2%, respectively. The Northern Manhattan Study showed that the 5-year risk of MI was 8.6% in patients with stroke, though more research is needed to detect the determinants of MI after stroke.⁴ However, due to the essential characteristics of observational studies, these studies still cannot control the effects of unmeasured confounding factors and reverse causality. This study observed that the causal

effect of all ischemic stroke on MI was weakened in the two sample MR analysis using six SNP instruments, which excluded SNPs associated with diabetes, hypertension, atrial fibrillation, and coronary heart disease, indicating that the causal effect of all ischemic stroke on MI may be mediated by these factors.

Regarding the effect of LAS on MI, causality persisted after using the three SNP instruments, which excluded a SNP (rs2107595) that had been associated with self-reported hypertension or coronary artery disease, indicating that their causal association is robust. This study provides evidence supporting a causal relationship of genetically predicted LAS on the risk of MI using the two-sample MR method, which may control unmeasured confounders and reverse causation.¹³ This is a significant finding that may help to clarify the internal association between LAS and MI. As is well-known, LAS subtype and MI share many common atherosclerotic factors,³¹ which may indicate that there is a correlation between them. Brain injury can change the autonomic nervous and neurohormonal pathways involved in the control of heart function,^{5,32} so stroke patients are prone to serious adverse cardiac events that further affect cardiac function and promote myocardial injury. From a mechanistic and pathophysiological perspective, the main reasons for the increased risk of MI after stroke are as follows: changes in the structure or function of the central autonomic neural network³³ (especially the activation of the renin-angiotensin-aldosterone system); microvascular dysfunction;³⁴ systemic proinflammatory response,³⁵ and coronary artery demand ischemia.⁶ Given the high clinical burden of MI after ischemic stroke,³⁶ high-quality monitoring of cardiovascular adverse events should be maintained for stroke patients. This research emphasizes the importance of the diagnosis and treatment of LAS and its causes, not only to prevent the recurrence of stroke but also the occurrence of myocardial infarction.

Prospective observational studies have demonstrated that MI is associated with stroke.³ Stroke is a serious complication of MI, and there is a high risk of ischemic stroke within one year after MI.⁸ In addition, ischemic stroke after MI is related to high mortality and morbidity, resulting in a heavy clinical burden.³⁷ Left ventricle akinesia and/or dyskinesia after MI possibly increase the risk of mural thrombosis and cause stroke or peripheral thromboembolism.⁹ However, in this study, MI showed no causal effect on stroke and its subtypes using the two-sample MR method. This result suggests that the relationship between MI and stroke risk detected in observational cohort studies may be confounded by common risk factors, rather than indicates causality. As is well-

known, MI and stroke have numerous common vascular risk factors, such as age, smoking, obesity, lipid disorders, diabetes mellitus, hypertension, heart failure, and atrial fibrillation.³⁸ As our results demonstrate, after excluding SNPs related to these risk factors, the causal effect of MI on stroke is not significant. Therefore, it is critical to manage risk factors, in order to prevent the occurrence of stroke after MI. However, the summary level of the GWAS dataset can hardly eliminate the effect of other confounding factors and avoid the sub-threshold effect of the genetic variants. Therefore, the causal effect of MI on stroke and its subtypes needs to be further investigated.

This study has some limitations. First, stroke and MI share many common risk factors; although we screened each SNP, there are still some potential factors that cannot be adjusted. Second, the potential horizontal pleiotropy cannot be entirely excluded, which may cause biased causal effect estimates, although pleiotropic effects were not found in the test of this study. Third, the subjects of this MR study were of European ancestry, and it cannot be completely ruled out that population stratification may have some influence on the results. Thus, this conclusion should not be generalized to other ethnic groups worldwide. Finally, there are only a few SNPs associated with LAS at a genome-wide significance level, and they cannot reliably detect the abovementioned pleiotropy with the alternative MR methods. Thus, functional SNPs in the up-to-date GWASs should be used for further MR analysis to confirm the conclusion.

Conclusion

This MR analysis provides evidence to support the causal effect of LAS subtype on MI, and some factors act as confounding factors whereas others may act as mediators.

Data Sharing Statement

In this study, all data were derived from publicly available Open GWAS project database (<https://gwas.mrcieu.ac.uk/>), and all data can be obtained for free.

Ethics Statement

All data in this study were obtained from Open GWAS project database (<https://gwas.mrcieu.ac.uk/>), which has been published previously. This article does not include any studies with human participants or animals performed by any of the authors, therefore ethical approval was not needed.

Acknowledgments

We are grateful to the investigators of MEGASTROKE and CARDIoGRAMplusC4D consortia for making their results publicly available, and thank all participants for their contribution to this study.

Funding

This research was supported by the National Key Research and Development Program, Major Chronic Non-Communicable Disease Prevention and Control Research Key Special Project (2017YFC1308202), and Henan Provincial Medical Science and Technology Research Plan (SBGJ2018031).

International Journal of General Medicine

Dovepress

Publish your work in this journal

The International Journal of General Medicine is an international, peer-reviewed open-access journal that focuses on general and internal medicine, pathogenesis, epidemiology, diagnosis, monitoring and treatment protocols. The journal is characterized by the rapid reporting of reviews, original research and clinical studies

across all disease areas. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-general-medicine-journal>
