ABSTRACT

Bacterial wound infections are a growing challenge in healthcare, posing severe risks like systemic infection, organ failure, and sepsis, with projections predicting over 10 million deaths annually by 2050. Antibacterial hydrogels, with adaptable extracellular matrix-like features, are emerging as promising solutions for treating infectious wounds. However, the antibacterial properties of most of these hydrogels are largely attributed to extrinsic agents, and their mechanisms of action remain poorly understood. Herein we introduce for the first time, modified imidazolidinyl urea (IU) as the polymeric backbone for developing tissue-like antibacterial hydrogels. As-designed hydrogels behave tissue-like mechanical features, outstanding antifreeze behavior, and rapid self-healing capabilities. Molecular dynamics (MD) simulation and density functional theory (DFT) calculation were employed to well-understand the extent of H-bonding and metal-ligand coordination to finetune hydrogels' properties. *In vitro* studies suggest good biocompatibility of hydrogels against mouse fibroblasts & human skin, lung, and red blood cells, with potential wound healing capacity. Additionally, the hydrogels exhibit good 3D printability and remarkable antibacterial activity, attributed to concentration dependent ROS generation, oxidative stress induction, and subsequent disruption of bacterial membrane. On top of that, *in vitro* biofilm studies confirmed that developed hydrogels are effective in preventing biofilm formation. Therefore, these tissue-mimetic hydrogels present a promising and effective platform for accelerating wound healing while simultaneously controlling bacterial infections, offering hope for the future of wound care.

1. Introduction

Since the 21st century, bacterial infections have become a formidable challenge in healthcare [1], with surgical site infections (SSIs) and urinary tract infections (UTIs) representing approximately 55 % of incidence among nosocomial infections as reported in 2002 [2]. It is estimated that by 2050, humankind will face a staggering toll, with over 10 million annual deaths attributed to bacterial infections, surpassing all other causes of mortality-including cancer [3]. Bacterial wound infections caused by pathogenic bacteria prolong the healing process and pose significant risks of systemic infection, organ failure, and sepsis,

underscoring an urgent need for effective interventions [4]. Although the discovery of antibiotics initially curbed the advancement of bacterial infections, drug abuse has led to antibiotic-resistant strains among pathogenic bacteria [5]. To counter such challenges, varieties of innovative materials with antimicrobial properties have been developed, such as nanomaterials [6,7], foam [8,9], nanofibers [10,11], and hydrogels [12–15]. Among these agents, hydrogels with tunable tissue-like features, remarkable absorption capability, biodegradability, biocompatibility [14,16], and extracellular matrix (ECM)-like porous structure have emerged as the most promising candidates for bacterial-infected wound treatments. However, the most reported

---

antibacterial hydrogels rely on incorporating additional active compounds, such as drugs or nanomaterials, instead of inherent antibacterial characteristics [17–19]. These investigations have not paid enough attention to the origins of antibacterial activities and how they lead to bacterial death.

In general, antibacterial agents inactivate bacteria mainly by damaging their membranes, preventing the production of cell walls, targeting intercellular molecules, and by immunomodulation [20]. Many cationic polymers kill bacteria through electrostatic interaction, followed by hydrophobic insertion into lipid tails and subsequent membrane lysis [21–23]. Moreover, they can inhibit the production of cell walls by targeting lipid II [24,25], a crucial precursor in the biosynthesis of peptidoglycan layers, ultimately leading to disruption of bacterial growth. When targeting intercellular molecules, specific antibacterial agents can overcome the barriers posed by the outer membrane and cytoplasmic membrane [26,27]. These agents may accumulate within the cytosol, strongly interact with DNA, inhibit cell division, condense bacterial chromosomes, and inhibit nucleic acid synthesis to disrupt critical intracellular processes. For immunomodulatory mechanisms, antibacterial agents effectively recruit immune cells like neutrophils, macrophages, and T cells to the infection sites, thereby promoting bacterial clearance. Moreover, they can also enhance neutrophil function, suppress the release of pro-inflammatory cytokines, facilitate the induction of anti-inflammatory cytokines, and promote phagocytosis [28,29]. Hence, a thorough investigation into deciphering the mechanism provides a deeper understanding of the intricate relationship between their structure, properties, and efficacy against various microbial species, guiding more effective antimicrobial materials' development.

In addition to exploring antibacterial mechanism studies, another challenge is designing innovative multifunctional materials. Urea and its derivatives play a significant role in medicinal applications, such as modulating drug potency, selectivity, and pivotal interactions with drug targets [30]. In recent years, several urea derivatives have emerged as effective antimicrobial agents, offering promising solutions to fight against microbial infections [31–33]. Imidazolidinyl urea (IU) is an antimicrobial preservative used to formulate pharmaceutical products, cosmetics, and household detergents [34]. Recently, with increasing attention to preservatives, more research has been devoted to the IU molecule. For example, Wang et al. prepared the IU-grafted reverse osmosis membrane, in which IU acted as both the antimicrobial agent and the precursor of N-halamine. A reversible transition between N-Cl and N-H groups happened during sterilizing microbial cells and the chlorination process [35]. Apart from chemical and biological functionalities, rich H-bonding donors and receptors from IU could promote the formation of multiple hydrogen bonds. For example, Cheng's group has reported H-bonding reinforced biocompatible hydrogels and observed that the introduction of IU contributed to superior mechanical properties, self-healing and shape memory abilities, and degradability [36–40]. Moreover, IU-based hydrogels were utilized as tannic acid-loading carriers for diabetic wound healing and infectious skin treatments [41], as tannic acid/kartogenin-loading scaffold for *in vivo* cartilage regeneration [40]. In our recent work, we designed IU-based photoresins for high-resolution 3D printing, and the printed objects exhibited potent antimicrobial activity [42]. Overall, all these studies exploited its promising potential in both structural superiorities and functionalities. However, in most of these studies, IU was utilized either as a small molecule, an additive or as a part of a structural backbone without evaluating its biological performance and intrinsic antibacterial mechanism of action in detail.

In this study, for the first time, we incorporated a modified IU molecule as the polymers' backbone and explored its inherent biological properties, especially antibacterial performance and its mechanisms. By integrating both structural and functional advantages, we have developed several IU-based tissue-like hydrogels through free radical polymerization under mild conditions. Dynamic metal-ligand coordination

was introduced into the system to tune mechanical properties, such as strength, modulus, and fatigue. Tensile/compression tests and density functional theory (DFT) calculation were combined for formulation optimization. In addition to structural and morphological characterization (NMR and SEM), FTIR and molecular dynamics (MD) simulation were utilized for hydrogen bonding investigation, followed by antifreeze, rheological, and self-healing behavior studies. Then, we evaluated *in vitro* cytocompatibility of designed hydrogels against three distinct cell lines NIH/3T3 mouse fibroblasts, BEAS-2B human lung epithelial cells, and HaCaT human keratinocytes, assessed hemocompatibility against human red blood cells, and conducted *in vitro* wound healing assay. Furthermore, we studied their antibacterial performance against both gram-negative *Escherichia coli* (*E. coli*) and gram-positive *Bacillus subtilis* (*B. subtilis*); followed by an in-depth investigation to unravel the intrinsic antibacterial mechanism through an amalgamation of both experimental and theoretical (MD simulation) strategies. Lastly, we studied their capabilities to prevent biofilm formation.

2. Results and discussion

2.1. Synthesis and mechanical study

We synthesized acylated IU monomer under mild conditions from commercial cosmetic preservative imidazolidinyl urea (IU, Scheme S1); the structure was confirmed by FTIR (Fig. S1), ^{1}H NMR (Figs. S2 and S3), and ^{13}C NMR (Fig. S4). In Fig. S1, new peaks at 862 and 3066 cm^{-1} correspond to the C=C bending and C-H stretching of C=C, respectively, indicating the successful incorporation of the acrylate group within the IU structure. Furthermore, new peaks at 5.86, 6.01, and 6.27 ppm from ^{1}H NMR (Figs. S2 and S3) indicate the presence of acrylate protons. On the other hand, two new peaks are observed at 129 and 131 ppm in ^{13}C NMR (Fig. S4) belonging to acrylate carbons, which strongly confirms the successful synthesis of IU monomer. Then, IU-based hydrogels were prepared by copolymerizing IU monomer and methacrylamide (MAA), via free radical polymerization using ammonium persulfate (APS) as initiator and N,N,N′,N′-tetramethylethylenediamine (TEMED) as a catalyst in deionized water at 37 °C (Fig. 1a, Fig. S5). The optimization of formulations and conditions was based on the mechanical (tensile and compression) tests (Fig. S6). After optimization, at a molar ratio of 1:2.5 between IU monomer and MAA and 50 % of monomer concentration, we obtained a soft and highly stretchable hydrogel PMIU (Fig. S7). The excellent stretchability is attributed to the enriched hydrogen bonding facilitated by the imidazolidinyl urea structure [37,41]. However, it has poor physical stability and is soluble in water, which demands further improvement in its mechanical properties. For emerging applications such as artificial tissues and wound healing dressings, materials must maintain stability and durability under prolonged mechanical stress, resisting cyclic fatigue damage or fracture [43]. In this regard, we opted for dynamic metal-ligand coordination instead of covalent crosslinking to enhance hydrogel's stability and mechanical strength, with the accessional value of reversible response under damage, such as self-healing capability. Therefore, we introduced a low ratio of vinyl imidazole (VI) and Ni^{2+}/Zn^{2+} salts into the PMIU system; the imidazole moiety as an integral component of specific amino acids found in various peptides [44], which can coordinate with different metals for constructing and tuning metallogels' performance and behavior [45,46]. From the optimization, there was no significant improvement in hydrogels' mechanical performance by introducing a low amount of vinyl imidazole, only if metal ions Ni^{2+}/Zn^{2+} were present to trigger metal-ligand coordination. With the increase of vinyl imidazole and related metal ions, the mechanical properties of synthesized hydrogels increased, and the materials became stiffer. Whenever the molar ratio of vinyl imidazole and IU monomer is above 0.5, the precursor solution will be crosslinked quickly after initiation of polymerization. This sudden increase in viscosity is attributed to the strong metal-ligand
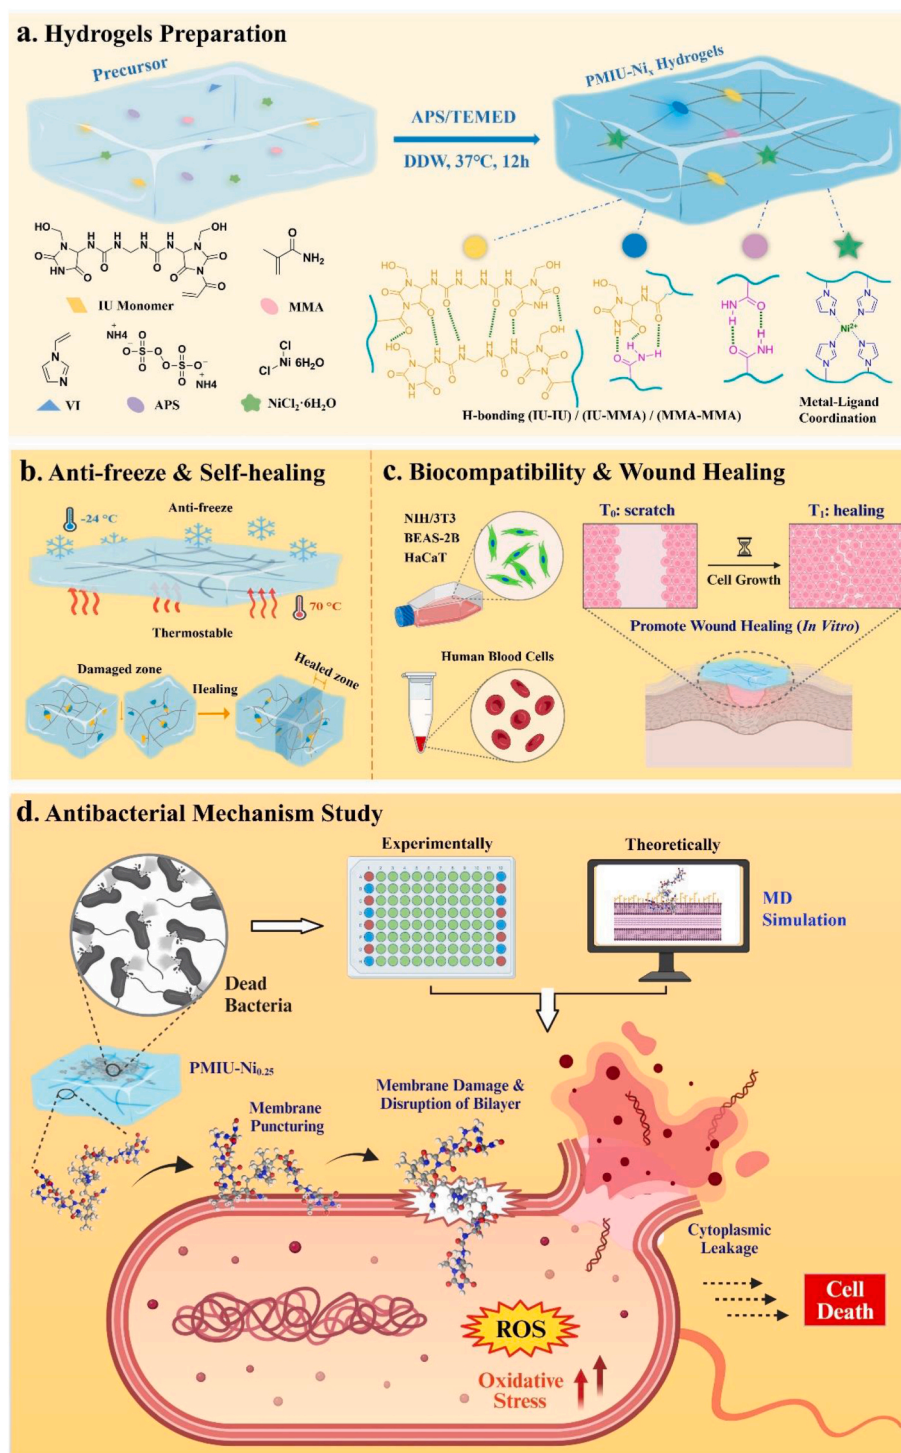

Fig. 1. Schematic illustration of this work. a) Hydrogels preparation; b) Anti-freeze and self-healing; c) Biocompatibility and wound healing; d) Antibacterial mechanism study.

coordination and H-bonding interactions that took place simultaneously. However, we are aiming to design tissue-like hydrogels for biomedical applications, therefore we chose the molar ratio between IU monomer and vinyl imidazole of 4:1 to balance the mechanical performance and flexibility.

Here, several metal-ligand reinforced hydrogels PMIU-Ni$_x$ and PMIU-Zn$_y$ were synthesized, where x (0.125, 0.25 and 0.5) and y (0.125, 0.25 and 0.5) stand for the ratios between Ni^{2+}/Zn^{2+} and VI, respectively. Fig. 2a and c represent tensile and compression stress-strain curves for all IU-based hydrogels, respectively. Polymethacrylamide (PMAA)

hydrogel was used as a control. For hydrogels PMIU-Zn$_y$, mechanical properties increased with the increase of the Zn^{2+} ratio. While for PMIU-Ni$_x$, PMIU-Ni$_{0.25}$ shows the best balance between the tensile strength of 214.71 $\pm$ 3.94 kPa and strain of 477.07 $\pm$ 34.64 % (Fig. S8), with the elastic modulus of 471.19 $\pm$ 17.52 kPa and toughness of 623.665 $\pm$ 84.82 kJ/m^3 (Fig. 2b). Similarly, for the compression tests, PMIU-Ni$_{0.25}$ also exhibits remarkable compressive strength (447.26 $\pm$ 28.26 kPa), strain (86.32 $\pm$ 3.91 %), stiffness (77.34 $\pm$ 4.83 kPa), and toughness (69.16 $\pm$ 4.25 kJ/m^3), as shown in Figs. S8 and 2d. In particular, the hydrogel PMIU-Ni$_{0.125}$ shows better mechanical performance than

PMIU-$Zn_{0.5}$, indicating that more efficient chelation occurred between Ni^{2+} and the imidazole group than Zn^{2+}. To quantitatively assess the metal-ligand coordination in this system, we calculated the binding energy between Ni^{2+} and different numbers of imidazole ligands (1–6) using density functional theory (DFT) calculation (S1.7, ESI). Interestingly, the optimized structures in Fig. 2e, one ligand of $Ni^{2+}\cdot(VI)_5$ and two ligands of $Ni^{2+}\cdot(VI)_6$ dissociated from Ni^{2+}, respectively. The binding energies of both structures are approximate to $Ni^{2+}\cdot(VI)_4$.

Meanwhile, from Table S1, both optimized $Ni^{2+}\cdot(VI)_5$ and $Ni^{2+}\cdot(VI)_6$ structures have 4 equal $N-Ni^{2+}$ bonds with bond length around 1.94 Å, same as $Ni^{2+}\cdot(VI)_4$ (Fig. 2f). While $Ni^{2+}\cdot(VI)_5$ has another different $N-Ni^{2+}$ bond with a length of 3.62 Å, and $Ni^{2+}\cdot(VI)_6$ has two different bonds with lengths of 2.93 and 3.53 Å, proved that the dissociation between Ni^{2+} and part of imidazole ligands takes place. Concluding the binding energy and bond length distributions of these three structures, the ratio of 1:4 between Ni^{2+} and imidazole ligand resulted in the

optimum coordination. This quantitative calculation coincides well with tensile/compression results, that the hydrogel PMIU-Ni$_{0.25}$ exhibits pioneering mechanical performance. Overall, the designed hydrogels achieved a comprehensive improvement in stretchability and strength compared to PMAA hydrogel, by collaborating rich hydrogen bond interactions along with dynamic reversible metal-ligand coordination [47, 48]. According to mechanical properties, we featured hydrogels PMIU (as a reference) and PMIU-Ni$_{0.25}$ for further studies. Figs. S9, 2g, 2h, and 2i illustrate the robust mechanical properties of PMIU-Ni$_{0.25}$ hydrogel. A hydrogel ribbon (~2 mm, 1 g) was stretched in normal, knotted, and twisted conditions and still was able to withstand the high strain. In addition, it could lift ~256 g of weight without rupture, indicating superior mechanical strength. Also, Fig. S10 clearly shows the tissue-like flexibility of PMIU-Ni$_{0.25}$ hydrogel, which could repeatedly bend on the finger and elbow between 90 and 180°. Moreover, five hydrogel cylinders could take a person (~60 kg) without evident collapse, as shown in Fig. 2j. This could mainly attributed to diverse physical interactions of H-bonding, especially metal-ligand coordination, as sacrificial bonds that strengthen mechanical properties, including toughness. Toughness would help to dissipate energy during the sample deformation but possibly cause fatigue, implying the degradation of hydrogel properties [49].

Inspired by this observation and hypothesis, we investigated the fatigue of hydrogel PMIU-Ni$_{0.25}$ by cyclic tensile loads. From Fig. S11, dissipated energy (hysteresis area between loading and unloading curves) increases with strain percentages, around 65–80 % of the total work. When stress is applied, energy will be dissipated due to the breakage of sacrificial bonds; the broken inter-chain reversible bonds will change the network topologies of hydrogels, where the network topologies will significantly affect the fatigue behavior. Lin et al. introduced partially crystalline structures in polyvinyl alcohol hydrogels and achieved a superior fatigue threshold exceeding 1000 J/m^2 [43]. The required energy per unit area for fracturing fatigue cracks in highly ordered networks was much higher than in a single layer of polymer chains. Here, ten loading-unloading cycles were proceeded with PMIU-Ni$_{0.25}$ to quantify the cyclic fatigue damage at 200 % strain. From Fig. 2k and l, a substantial hysteresis loop is observed in the 2nd cycle with 50 % dissipated energy and 20 % strength drop; the cyclically applied loads without rest caused ongoing damage to sacrificial bonds. Interestingly, after 6 cycles, both dissipated energy and strength started to increase, possibly due to the partial rejoint of the broken sacrificial bonds, which helped to rebuild the disordered networks. Also, fatigue crack-resistant effects in different directions of 3D networks amplify the antifatigue behavior [46,50]. Inspired by this interesting observation, a second loading-unloading cycle was conducted on the first cycle sample but after a 5-min rest. As expected, almost no hysteresis of the loading-unloading loop is observed (Fig. 2m and n), and the dissipated energy and strength recovery to 95 % and 103 % of the original hydrogel, respectively. Meanwhile, fatigue of PMIU-Ni$_{0.25}$ was also studied by cyclic compression loads at 60 % strain; similar conclusions as tensile loads vide supra (Fig. S12). In sum, the above results reveal that the hydrogel PMIU-Ni$_{0.25}$ possesses robust fatigue resistance properties under multiple cycles of loads and extraordinary recovery characteristics.

Fatigue correlates with rheology, a liquid-like hydrogel will relax to zero stress under a prolonged static stretch without increasing static and cyclic fatigue threshold. Meanwhile, a solid-like hydrogel relaxes to finite stress (nonzero) and with an increase in static fatigue threshold [49]. Stress relaxation seeks to understand the mechanism of hydrogel fracture and fatigue differently. In this work, we studied the stress relaxation behavior of PMIU-Ni$_{0.25}$ at different strains. From Fig. 2o, similar trends of stress evolution versus time are observed from different strain curves: a rapid drop followed by a nonzero plateau, indicating the solid-like behavior of the hydrogel. Like uniaxial tensile stretch, stress comes from sacrificial bonds and drives the chain segment orientation during loading. During relaxation, a dramatic stress reduction is

ascribed to the breakage of sacrificial bonds, which could weaken inter-chain interactions and cause the relaxation of chain segment orientation. Although efficient recovery happens, rebuilt networks are relaxed, without contributing to strain energy and chain order [51]. Constant stress at a nonzero plateau relies on the elasticity of the inherent polymer chains and entangled networks [52]. To concretely describe the viscoelastic behavior, the stress relaxation data was fitted by the model combining two viscoelastic (Maxwell) and one elastic (Viogt) elements in parallel (Fig. S13). From Fig. 2p, the theoretically fitted curves of PMIU-Ni$_{0.25}$ at 100 %, 200 %, 300 %, and 400 % strains highly match the experimental data, with squares of the correlation coefficient exceeding 0.995.

Hence, the stress relaxation behavior is described as Equation (1):

$$\sigma_t = \sigma_1 + \sigma_2 + \sigma_3 = E_1 \varepsilon_0 \exp(-(t-t_0)/\tau_1) + E_2 \varepsilon_0 \exp(-(t-t_0)/\tau_2) + E_3 \varepsilon_0 \tag{1}$$

Where σ_t is the total stress, σ_i and E_i are the stress and elastic modulus of each unit, respectively. ε_0 is the constant initial strain, t_0 is the initial relaxation time. τ_i is the response of the one-dimensional Maxwell element, represented by the ratio of viscosity η_i to elastic modulus E_i, $\tau_i = \eta_i/E_i$.

Meanwhile, the relaxation modulus E_r can be calculated by Equation (2):

$$E_r = \sigma_t / \varepsilon_0 = E_1 \exp(-(t-t_0)/\tau_1) + E_2 \exp(-(t-t_0)/\tau_2) + E_3 \tag{2}$$

All characteristic parameters related to Equations (1) and (2) are shown in Table S2.

2.2. Physical study

The microstructure of IU-based hydrogels was analyzed by a high-resolution scanning electron microscope (HR-SEM). Fig. 3a and b shows that both hydrogels exhibit three-dimensional (3D) networks, while a denser and more orderly packed network is observed at the PMIU-Ni$_{0.25}$ network. Average pore size distribution curves fitted by the Gaussian function show a more uniform microstructure with homogenous pores in PMIU-Ni$_{0.25}$ compared to PMIU. The dynamic covalent bonds between Ni^{2+} and imidazole moiety are the dominant contribution for driving the network organization, instead of physical cross-linking through polymer chain entanglement and multiple H-bonding interactions [53,54]. Next, FTIR was employed for hydrogel structural characterization, as shown in Figs. S14 and S15, the spectrums evidence the successful synthesis of hydrogels. To further investigate the H-bonding interactions, we analyzed the FTIR spectrums of hydrogels PMIU and PMIU-Ni$_{0.25}$ from 1740 to 1500 cm^{-1} and fitted it with the Gaussian function, as shown in Fig. 3c and d. For both hydrogels, fitted curves closely match the experimental curves, and 7 separate peaks are obtained; where peaks I, II, III, IV, and V are related to H-bonded C=O, free C=O, H-bonded C=O, H-bonded C=O, and free amide, respectively. In addition, peaks VI and VII for PMIU indicate the existence of H-bonded N-H and free N-H. For PMIU-Ni$_{0.25}$, peak VI belongs to a free N-H bending, while peak VII belongs to an H-bonded N-H [55]. Furthermore, we utilized Molecular Dynamics (MD) simulation to further analyze hydrogen bonds composition. Three representative cubic boxes were constructed to simulate the experimental hydrogel systems and optimized by a Forcite module with a COMPASS II force field. Due to the lack of Ni^{2+} ion in this force field, we built a PMIU-Zn$_{0.5}$ hydrogel system instead of PMIU-Ni$_{0.25}$ (S1.8, ESI). Fig. 3e–S16, and 3g represent the equilibrium state of PMIU, PMIU-VI, and PMIU-Zn$_{0.5}$, respectively. Meanwhile, snapshots of optimized structures shown in Fig. 3f and h intuitively exhibit the H-bonding interactions between different moieties. After equilibrium, different types and numbers of hydrogen bonds were counted and analyzed, as shown in Fig. 3i. In all systems, more than 70 % of H-bonds comes from inter IU monomers, IU monomer and water molecule, IU monomer and MMA, proving the

dominant H-bonds contribution from imidazolidinyl urea as expected. And the H-bonds distributions between PMIU and PMIU-Zn$_{0.5}$ systems further match the experimental results, that the hydrogels PMIU-Ni$_x$ and PMIU-Zn$_y$ sustained surprised flexibility and stretchability after metal-ligand chelation, with substantial improvement in mechanical performance.

Besides H-bonding analysis, thermostability and anti-freeze properties of synthesized hydrogels were also evaluated using Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC). For

biomaterials and devices, extraordinary behaviors under extreme environmental conditions are indispensable to maintain their mechanical stability, conductivity, and other functionalities [56]. The TGA results from Fig. S17 prove the superior water retention capacity and thermal stability of hydrogels at high temperatures. Step I indicates the moisture loss; step II (after 220 °C) is mainly related to the decomposition of the imidazolidinyl urea structure and followed by the decomposition of polymethacrylamide (step III). Fig. 3j represents DSC curves (cooling from 25 °C to −60 °C and then warming to 25 °C) of PMIU and

PMIU-Ni$_{0.25}$ hydrogels; the crystallization/freezing peaks observed at −22.58 and −24.08 °C demonstrating their advanced freeze-tolerant performance to maintain physical performance under extreme cold environment. The mechanisms of antifreeze behavior are mainly H-bonding, structure of components, and chelation effects. Firstly, rich hydrogen bonds between water molecules and polymer structures

significantly enhanced hydrogels' moisture-holding capability and freeze tolerance. Meanwhile, introducing hydrophobic moieties (methyl groups) and urea structures into hydrogels could lower the freezing point [57]; the hydrophobic aggregates confined the growth of ice nuclei to proceed with crystallization [58], coincident conclusion as Janus effect of antifreeze proteins (AFPs) that hydrophobic ice-binding face of

AFPs inhibit ice formation [59]. Notably, from Fig. 3j, the crystallization of PMIU-Ni$_{0.25}$ happens 1.5° lower than PMIU, likely due to the freezing point depression effect of inorganic salt NiCl$_2$ [60], and denser microstructure (less distance) after chelation, which affects the hydrophobic inhibition efficacy of ice growth [61].

Lastly, to quantitatively assess the flow/deformation of synthesized hydrogels, the rheological properties, especially viscoelastic behavior, were investigated using an oscillatory rheometer. Most hydrogels are non-Newtonian liquids with shear-thinning behavior, where the viscosity decreases as the shear rate increases [62]. As shown in Fig. S18, a higher zero-shear viscosity of PMIU-Ni$_{0.25}$ compared to PMIU is observed, which is due to the higher toughness of PMIU-Ni$_{0.25}$. At the same time, PMIU shows better viscosity maintenance during shear thinning, where its flexible network contributed to less viscosity drop. In addition, temperature sweep results in Fig. S19 indicate favorable thermal stability of both PMIU-Ni$_{0.25}$ and PMIU, consistent with TGA analysis data. Viscoelastic materials generally show viscous and elastic behavior during deformation, while purely elastic materials do without energy dissipation. Storage modulus G′ represents stored deformation energy (i.e., stiffness), and loss modulus G″ reflects dissipated energy (i.e., flow) are defined to describe materials' viscoelastic behavior during the shear process [63]. In this work, we conducted oscillatory strain sweep tests on hydrogels at a frequency of 1 Hz to the abstract linear viscoelastic region (Fig. 3l and n). According to the results, a strain of 0.1 % was opted for frequency sweep experiments. In Fig. 3k and m, PMIU-Ni$_{0.25}$ shows more elastic/solid-like behavior while PMIU shifted from viscous to elastic behavior with the increase of frequency. Additionally, the moduli of PMIU-Ni$_{0.25}$ are much higher than PMIU, corresponding to more preceding stiffness and strength contributed by metal-ligand coordination and lower flexibility, as shown in the mechanical study.

2.3. Self-healing study

In general, self-healing hydrogels can be used as wound-healing dressings, artificial tissues, biosensors, and actuators [64,65]. A schematic diagram of hydrogel's self-healing and stretching processes is shown in Fig. 4a, with both damaged and healed zones, illustrating the rejoining of sacrificial bonds after damage and their behavior while stretching. This healed zone is the weak point of the sample, challenging the healing capacity of sacrificial bonds for energy dissipation, to resist the growth of cracks or fractures instead of a homogenous recovered fatigue system. To evaluate the self-healing performance of designed hydrogels, we cut both prepared PMIU and PMIU-Ni$_{0.25}$ into two segments (one colored by Congo red), and attached them together for healing, as shown in Fig. 4b and c. For soft hydrogel PMIU, the self-healing happened at body temperature within a half hour. While for stiffer hydrogel PMIU-Ni$_{0.25}$, we tracked the self-healing process after 1h, 2h, and 4h, respectively. As expected, both healed hydrogels exhibit excellent stretchability. Also, after 2h healing, PMIU-Ni$_{0.25}$ could still lift 256 g of weights (Fig. 4d). Then, the self-healing efficiency of PMIU-Ni$_{0.25}$ at different time points was checked by mechanical tensile test. Fig. 4f shows the strength and stretchability recovery percentage calculated from stress-strain curves (Fig. 4e). Compared to the original hydrogel, after 2h, the stress of PMIU-Ni$_{0.25}$ can recover to around 72.28 %, and strain can return to 75.43 %; while after 4h, stress and strain can recover to about 85.3 % and 89.82 %, respectively. This result strongly indicates the fast and excellent self-healing performance. In addition to that, we performed step-strain sweep (thixotropic) experiments to assess the intrinsic self-healing capacity. Synthesized hydrogels were tested under the alternative applied strain of 0.1 % (linear viscoelastic region) and 100 % (non-linear region) at a constant frequency of 1Hz, 40 s for each application. Fig. 4g and h shows that storage and loss moduli at the strain of 0.1 % decreased and reversed instantly when 100 % of the strain was applied. The deformation of hydrogel networks happens within a nonlinear regime, in which modulus is the function of strain

amplitude. Then, the modulus effectively recovered toward the original state upon returning to 0.1 % of the strain, indicating reattachment of sacrificial bonds, which leads to the network reconstruction. This alternative modulus changes behavior under step-strain reveals shear-induced reversible gel-sol transition of synthesized hydrogels. In this system, the self-healing mechanism mainly involves H-bonding interactions, reversible metal-ligand coordination, and thermal effects. During healing, the broken H-bonds between molecules and water will reassociate at damaged zone; the recovered H-bonding will reconstruct the inter-chain interactions for crosslinking. For PMIU-Ni$_{0.25}$, dynamic Ni^{2+}-imidazole coordination happens in a short time except for H-bonding interactions; the rebuilt sacrificial bonds will strengthen the hydrogel networks, heal the damage, and efficiently recover its mechanical performance. As observed in Fig. 4g and h, compared to slight moduli loss of PMIU, almost 100 % moduli of PMIU-Ni$_{0.25}$ was recovered after two cycles, which is mainly due to the synergistic effect of dual crosslinking. Lastly, thermal effects from external heating will accelerate the polymer chains' movement and promote reassociation and crosslinking.

2.4. In vitro biocompatibility and In vitro wound healing

Assessing biocompatibility is essential to identify potential adverse effects of newly developed materials intended for biomedical applications [66]. In this study, Alamar blue assay [67] was used to evaluate the cytotoxicity of synthesized hydrogels against three distinct cell lines, NIH/3T3 mouse fibroblasts, BEAS-2B human lung epithelial cells, and HaCaT human keratinocytes for 7 days. Figs. S20 and 5a illustrate the cell viability in PMIU (soluble) and PMIU-Ni$_{0.25}$ (leach liquor) conditioned media, treated against control. No significant cytotoxic effects were observed for all except the BEAS-2B cells with PMIU. After one day, the cells treated with conditioned media of PMIU-Ni$_{0.25}$ didn't affect the normal metabolic activity cells as supported by excellent cell attachment similar to TCPS (control), with no statistically significant difference. Substantial cell growth is observed after 3 and 7 days, respectively, indicating that the leach liquor from PMIU-Ni$_{0.25}$ is non-cytotoxic in the long term. Moreover, to gain further significant insights into cellular activity, we performed live-dead semiquantitative fluorescence imaging (Fig. 5c-e); and examined cellular morphology (Fig. 5f-h) for all three cell types treated with standard media and conditioned media of PMIU-Ni$_{0.25}$. The nucleus was stained with DAPI, and the actin filaments of cells were stained with Alexa fluor phalloidin. For days 1, 3, and 7, all the cells display a healthy and evenly distributed pattern with no significant difference in control. The live-dead and cellular morphology demonstrate the effective communication between neighboring cells through filopodial protrusions, supporting the cell viability data and proving the non-cytotoxic nature of the leach liquor from PMIU-Ni$_{0.25}$. Besides cytotoxicity, the blood compatibility of synthesized hydrogels was studied via hemolysis assay on fresh human blood. For the hemolysis study, deionized water was used as positive control, and physical saline was used as negative control; the experiment and results are shown in Fig. 5b. Based on the ISO standard (ISO document 10 993-5 1992), a hemolysis index of less than 5 % (PMIU-Ni$_{0.25}$: 4.03 %) is considered safe.

Looking into the promising noncytotoxic nature, blood compatibility, self-healing property, tissue-like flexibility (Fig. S10), and 3D printability (Fig. S21) of the hydrogel PMIU-Ni$_{0.25}$, we assessed its potential for wound healing application by using *in vitro* wound healing assay on human keratinocytes (HaCaT). From Fig. 5i and j, significantly faster wound closure happens in the presence of conditioned media compared to control. At the beginning (0 h), around 500 μm of wound distance in both control and PMIU-Ni$_{0.25}$; however, after 12 h, the wound area dramatically reduced in PMIU-Ni$_{0.25}$ system (Fig. 5j2, almost 60 % wound closure) and after 24 h, fully recovery happened (Fig. 5j3). Whereas for control, only 20 % of the wound recovered after 12 h (Fig. 5j2), while 50 % of the wound closed after 24 h (Fig. 5j3). Fast
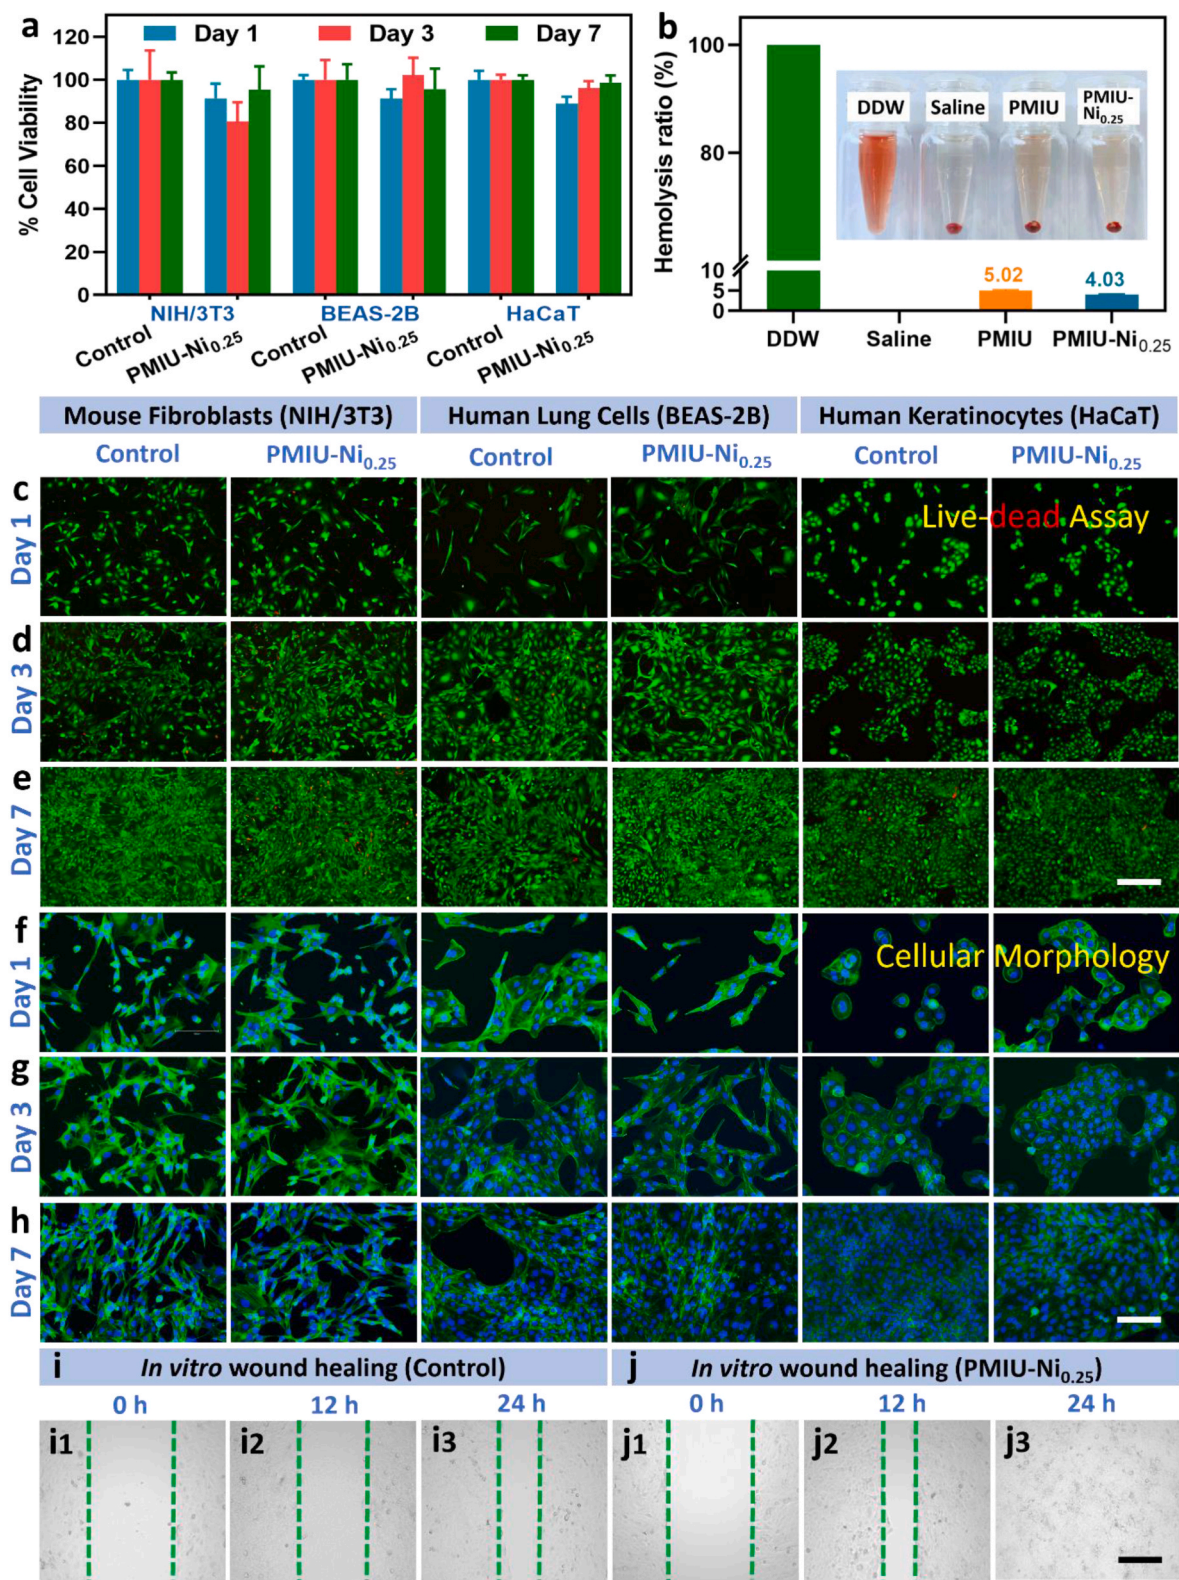

Fig. 5. *In vitro* biocompatibility and *in vitro* wound healing study. a) 1-, 3-, and 7-days cell viability of hydrogel PMIU-Ni$_{0.25}$ on three distinct cell lines, NIH/3T3 mouse fibroblasts, BEAS-2B lung epithelial cells, and HaCaT human keratinocytes. b) Blood compatibility of PMIU and PMIU-Ni$_{0.25}$, deionized water as the positive control, and physical saline as the negative control. Cellular morphology of hydrogel PMIU-Ni$_{0.25}$ on NIH/3T3, BEAS-2B, and HaCaT cell lines (scale bar, 150 μm), f) Day 1; g) Day 3; h) Day 7. *In vitro* wound healing assay on HaCat cell line for 24 h (scale bar, 300 μm), i) control; j) PMIU-Ni$_{0.25}$.

wound closure induced by PMIU-Ni$_{0.25}$ suggests it may possess good wound healing capability and be applicable for wound healing applications.

2.5. Antibacterial activity, mechanism and antibiofilm study

Inspired by the excellent mechanical properties, self-healing behavior, and *in vitro* cytocompatibility of synthesized hydrogels, we delved deeper into their antibacterial activity. Given the intrinsic antimicrobial properties of imidazolidinyl urea (Fig. S22) and vinyl imidazole [34,44], we anticipated that our developed hydrogels would exhibit notable efficacy against microbial threats. The antibacterial activity of the polymers PMIU & PMIU-Ni$_{0.25}$ was investigated against Gram-negative *E. coli* and Gram-positive *B. subtilis* using bacterial growth kinetics. The cells were treated with gradient concentrations of PMIU and PMIU-VI supplemented with Ni^{2+} salt (same as formulation of PMIU-Ni$_{0.25}$) for 12 h. The absorbance of untreated and treated bacterial suspensions was periodically measured at 600 nm. Fig. 6a1 and 6b1 present the growth curve of *E. coli* and *B. subtilis* treated with PMIU-Ni$_{0.25}$, clearly indicating that it inhibits both bacteria growth in a concentration-dependent manner. The minimum inhibitory concentrations (MIC) of PMIU-Ni$_{0.25}$ against *E. coli* is 1 mg/mL, and against *B. subtilis* is 0.7 mg/mL. Similar experiments were carried out for PMIU (Figs. S23a and S23b), which show identical MICs of 1 mg/mL and 0.7 mg/mL against *E. coli* and *B. subtilis,* respectively. Further investigations into understanding their bactericidal ability are shown in Fig. 6a2 and 6b2. No bacterial growth at concentrations ≥1 mg/mL for *E. coli* and ≥0.7 mg/mL for *B. subtilis*, revealing that PMIU-Ni$_{0.25}$ could not only inhibit the growth but ultimately kill the microorganisms (MBC). Similarly, for PMIU, no growth is observed on the LB plates at a concentration of 2 mg/mL for *E. coli* and ≥0.7 mg/mL for *B. subtilis* (Figs. S23c and S23d). The results of MIC, MBC, and bactericidal potential of different polymers are summarized in Table S4. The MBC/MIC ratio is widely considered a valuable parameter to evaluate the bactericidal potential of any antibacterial agent. An agent is supposed to be bactericidal if its MBC/MIC ratio is less than or equal to 4. We have observed that for both *E. coli* and *B. subtilis*, the MBC/MIC ratio of the polymers is much less than 4 (Table S4), thereby clearly establishing the bactericidal potential of the polymers.

To clearly understand the origins of developed polymers' antibacterial activities and how these polymers lead to bacterial death, firstly, we conducted an extensive Molecular Dynamics (MD) simulation study (300 ns), focused on the interactions between model bacterial membranes and polymer (oligomer, ESI) in an explicit solvent system. In a meticulously tracked sequence (Fig. 6c and d, S24, and 6e), our investigations unveil that the oligomer's strong propensity to establish close affiliations with and ultimately penetrate the upper membrane leaflet results in substantial alterations in several pivotal dynamic properties. Firstly, the Root Mean Square Deviation (RMSD) analysis discloses a discernible divergence between the RMSD profiles of the upper and lower membrane leaflets (Fig. 6f). This discrepancy was further substantiated by the pronounced RMSD fluctuations of the oligomer, specifically during the MD simulation's 200–275 ns timeframe, effectively corroborating the penetration event (Fig. 6g). Furthermore, the Deuterium Order Parameter analysis provides a keen insight into the differences in the acyl chains of the upper and lower membrane leaflets (Fig. 6h). These differences highlight the significant impact of the oligomer's interaction on the dynamical characteristics of the membrane. Moreover, the 3D surface plots for membrane Area per Lipid (APL) and bilayer thickness (Fig. 6i, j, 6k, and 6l) provide vivid visualizations of the substantial changes in the surface area and thickness of the membrane. This underscores the profound dynamical shifts within the upper membrane leaflet as a direct result of the monomer's interactions.

The comprehensive MD simulation provides a crucial, atomic-level perspective on the intricate dynamics of oligomer-membrane

interactions, showing the tendency of the active components to bind to and penetrate the bacterial membrane strongly. To further understand this process in greater detail, we next set out to experimentally evaluate the impact of the active components on bacteria and elucidate its mechanism of action. The effect of PMIU and PMIU-Ni$_{0.25}$ on the membrane integrity and morphology of *E. coli* and *B. subtilis* were studied using fluorescent dye-based membrane damage assays. Fig. 6m1 and 6n1 show the results of cFDA-SE leakage assay in *E. coli* and *B. subtilis*, respectively, upon treatment with PMIU and PMIU-Ni$_{0.25}$. 5 (6)-carboxyfluorescein diacetate succinimidyl ester (cFDA-SE) is a membrane permeable dye which is non-fluorescent in its esterified form. Upon entering cells, the intracellular esterases cleave the dye molecules' ester bond, thereby converting them into a fluorescent form [68]. Live bacteria with intact membranes retain the fluorescent dye molecules and appear green. However, cells with damaged or ruptured membranes result in leakage of the dye molecules to the outside, leading to an increase in extracellular fluorescence. Leakage of this fluorescent form of the dye from the bacterial cells is used as a direct parameter to study the membrane integrity of the cells. Treatment of *E. coli* and *B. subtilis* with PMIU and PMIU-Ni$_{0.25}$ resulted in physical disruption of bacterial membrane integrity, as evidenced in the concentration-dependent leakage of cFDA dye molecules from the treated cells. It is observed that the effect of PMIU-Ni$_{0.25}$ on damaging the membrane is more prominent compared to PMIU, which might be due to the combined action of PMIU and Ni ions on bacterial membrane integrity. The membrane damaging potential of PMIU and PMIU-Ni$_{0.25}$ was further confirmed by propidium iodide (PI) uptake assays, as shown in Fig. 6m2 and 6n2. PI can enter cells only if the membrane is damaged or compromised. PI binds to single and double-stranded nucleic acids upon entering cells, producing a strong red fluorescence. Treatment of both *E. coli* and *B. subtilis* with PMIU and PMIU-Ni$_{0.25}$ resulted in a concentration-dependent increase in the uptake of the PI dye molecules by bacteria, as seen from an increase in the PI fluorescence inside the cells. Again, the impact of PMIU-Ni$_{0.25}$ is more significant than PMIU's in damaging bacterial membranes. In addition to membrane damage, we also investigated whether the effect of polymers on bacteria could induce oxidative stress inside the cells, which can also contribute to their antibacterial actions. The levels of total intracellular ROS were measured in untreated and treated cells as an indicator of oxidative stress using the DCFH-DA assay. As seen from Fig. 6m3 and 6n3, treatment of both *E. coli* and *B. subtilis* with PMIU and PMIU-Ni$_{0.25}$ resulted in a concentration-dependent increase in the intracellular ROS levels, with PMIU-Ni$_{0.25}$ contributing towards more oxidative stress generation in comparison to PMIU. A 2.2-fold increase in ROS production concerning control is observed in *E. coli* treated with 2 × MIC of PMIU-Ni$_{0.25}$ compared to treatment with 2 × MIC of PMIU, which induced a 1-fold increase in ROS production. Similarly, a 2.6-fold increase in ROS production is observed in *B. subtilis* upon treatment with 2 × MIC of PMIU-Ni$_{0.25}$ in contrast to a ~0.9-fold increase in ROS production with PMIU. In addition to the polymers, IU also plays a key role in the antibacterial activities, which is a well-known antimicrobial agent, as reported [34,42,69]. The partial hydroxymethyl group of IU could hydrolyze in water, then a trace amount of formaldehyde will be slowly released via dehydration (Fig. S25). The high reducibility of the formyl group could denaturalize the protein of bacterial cells [35]. More specifically, the antimicrobial properties of imidazolidinyl urea compounds are based on their proposed mechanism of protein alkylation of sulfhydryl groups [69,70]. The above studies were further supported by live/dead fluorescence microscopy and SEM images. Untreated *E. coli* (Fig. 6m4) and *B. subtilis* (Fig. 6n4) show uniform green fluorescence, indicating live bacteria, whereas *E. coli* and *B. subtilis* treated with PMIU (Figs. S23e and S23f) and PMIU-Ni$_{0.25}$ (Fig. 6m6 and 6n6) while orange (merge of green and red channel) stain indicating membrane damage and cell death. Similarly, morphological evaluation of bacteria upon treatment with PMIU (Figs. S23g and S23h) and PMIU-Ni$_{0.25}$ (Fig. 6m7 and 6n7) reveal extensive signs of damage and deformation. Untreated

cells (Fig. 6m5 and 6n5) show smooth morphology with intact shape, whereas the treated cells appear rough and crumpled with numerous indentations.

After understanding antibacterial mechanisms, the antibacterial activity of PMIU and PMIU-Ni$_{0.25}$ hydrogels against *E. coli* and *B. subtilis* was tested by incubating the cells directly on their surface (Fig. 7a). This process was followed by plating the treated cells on an agar plate to check for the presence or absence of bacterial growth. *E. coli* (Fig. 7b) and *B. subtilis* (Fig. 7d), in the absence of hydrogel, show prominent growth on the agar plates. In contrast, upon direct contact with the hydrogel surface, no colony is observed on the plates, indicating the complete killing of the cells by the hydrogels (Fig. 7c and e, S26a, and S26b). The live/dead fluorescence imaging and SEM results further validate these results. Untreated bacteria (Fig. 7f and h) stain green, showing their viable nature, whereas cells treated with the hydrogel-stained orange represent death (Fig. 7g and i, S26c, and S26d). Similarly, bacteria grown without hydrogel display intact morphology with a smooth appearance (Fig. 7j and l). In contrast, those treated with the hydrogels show damaged and deformed structures, indicating extensive cell death (Fig. 7k and m, S26e, and S26f).

Finally, we evaluated the biofilm inhibition capacity by utilizing both polymer (PMIU-VI supplemented with Ni^{2+} salt (same as formulation of PMIU-Ni$_{0.25}$)) and PMIU-Ni$_{0.25}$ hydrogel. The antibiofilm inhibition study of the polymer was conducted using the well-known crystal violet assay [71] (ESI 1.17) and further supported by brightfield imaging to understand their antibiofilm activity at different concentrations. In detail, the bacterial cells were treated with gradient concentrations (0, 0.5 × MIC, MIC, and 2 × MIC) of polymer and then incubated under static for 48 h to form biofilms. From Fig. 7n and p, both control *E. coli* and *B. subtilis* bacteria form dense biofilms after 2 days, while significant differences are observed in polymers (MIC) treated groups (Fig. 7o and q). Fig. 7r represents the biofilm mass at different polymer concentrations. Almost no biofilm formed at MIC and 2 × MIC in both bacterial groups; even at low concentrations of 0.5 × MIC, significant biofilm mass difference occurred compared to controls. For the hydrogel inhibition study, a small pellet of PMIU-Ni$_{0.25}$ hydrogel was immersed inside the bacteria suspensions, with the same incubation conditions as above for biofilm formation; polymethacrylamide (PMAA) without antibacterial properties as control hydrogel performed same experiments. After 48 h, the biofilm formation on the hydrogel's surface was detected by SEM imaging. As shown in Fig. 7s and u, both *E. coli* and *B. subtilis* bacteria form uniform and dense biofilms on the control PMAA hydrogel surface. In contrast, no bacterium or biofilm is observed on the PMIU-Ni$_{0.25}$ hydrogel surface. Therefore, both polymer and hydrogel inhibition studies strongly indicate their superior antibiofilm activities in preventing biofilm formation in solutions and surfaces. In sum, all the results powerfully demonstrate the antibacterial nature of the designed hydrogels.

3. Conclusions

For the first time, we incorporated the modified IU molecule as the polymers' backbone and successfully synthesized several novel IU-based hydrogels: PMIU, PMIU-Ni$_x$, and PMIU-Zn$_y$. Mechanical and rheological studies and hydrogen bonding analysis indicated that introducing dynamic metal-ligand coordination enhances the hydrogel's performance, leading to increased strength and modulus, improved anti-fatigue properties, and more elastic-like behavior. PMIU-Ni$_{0.25}$ hydrogel was identified as the best candidate due to its superior balance of multiple functionalities. Due to the incorporation of multiple H-bonding and dynamic Ni^{2+}/Zn^{2+}-VI coordination, synthesized hydrogels demonstrated rapid self-healing characteristics with high recovery efficiency. These hydrogels could maintain their features between −22 and 70 °C, which is especially appropriate for extreme cold conditions. Rich hydrogen bonds between water molecules and polymer structures will significantly enhance the moisture-holding capability, and the

introduction of hydrophobic moieties (methyl groups) and urea structures could lower the freezing point, in which the hydrophobic aggregates confined the growth of ice nuclei to proceed with crystallization.

Furthermore, *in vitro* biocompatibility evaluation showed no significant cytotoxic effects of PMIU-Ni$_{0.25}$ against three distinct cell lines NIH/3T3 mouse fibroblasts, BEAS-2B human lung epithelial cells, and HaCaT human keratinocytes, as well as good hemocompatibility against human blood cells. In addition, an *in vitro* wound healing study proved that PMIU-Ni$_{0.25}$ could potentially promote wound healing. Moreover, polymers and hydrogels of PMIU and PMIU-Ni$_{0.25}$ exhibited excellent antibacterial activity against gram-negative *E. coli* and gram-positive *B. subtilis*. Intrinsic mechanism study involved extensive MD simulation of polymer-model bacterial membrane interactions and fluorescence-based experimental assays. The comprehensive MD simulation provided a crucial, atomic-level perspective on the intricate dynamics of oligomer-membrane interactions, showing the tendency of the active components to bind to and penetrate the bacterial membrane strongly. Further, experimental assays indicated that the polymers could penetrate and damage the bacterial membrane, and the induction of oxidative stress by concentration-dependent reactive oxygen species (ROS) generation will cause intracellular oxidative damage. Finally, the biofilm inhibition study of both polymer and hydrogel strongly indicated their superior antibiofilm activities, to prevent the biofilm formation in solutions and surfaces. In sum, all results strongly demonstrate the attractive material features and antibacterial nature of the designed hydrogels, which provide various potentials for infectious wound care, such as treating wound infections and promoting wound healing. Meanwhile, the 3D-printability of these hydrogels opens their promising applications in the future as carriers and scaffolds for drug delivery and tissue engineering. For example, as a drugs-loading antibiofilm dressing material, treating multi-drug-resistant bacterial infected wounds.
