The respiratory rhythm is generated within the network of inspiratory neurons in the pre-Bötzinger complex (pBC) and persists under highly variable neuronal input. The mechanism of pBC rhythm generation at the level of the network is an active area of debate and inquiry. A fraction of these inspiratory pBC neurons generate a stable bursting rhythm even when pharmacologically isolated from the network and likely contribute to the rhythm. Experiments indicate that the intrinsic bursting mechanism of these pacemaker neurons depends on either persistent sodium current or changes in intracellular Ca^{2+} . Motivated by experimental evidence obtained from these subpopulations of bursting neurons, we developed a two-compartment mathematical model of a pBC pacemaker neuron with two independent bursting mechanisms. The model explains a number of contradictory experimental results and is able to generate a robust bursting rhythm over a large range of parameters, with a frequency adjusted by neuromodulators.

For the somatic compartment of our model, we used a previously developed model of pBC pacemaker neurons [1]. In this model, action potentials are generated by a fast sodium current (I_{Na}) and a delayed rectifier potassium current (I_K), and the burst is terminated by slow inactivation of a persistent sodium current (I_{NaP}). The bursting in the dendritic compartment of our model follows the Ca^{2+} oscillations arising from periodic Ca^{2+} release from intracellular stores. Briefly, the activation of a G_q -protein cascade leads to an increase in the concentration of IP_3 , which binds to its receptor on the surface of the endoplasmic reticulum and initiates Ca^{2+} influx into the cytosol. A calcium-activated nonspecific cation current (I_{CaN}) then depolarizes the cell membrane in response to the increase in intracellular Ca^{2+}

concentration. This depolarizing potential spreads to the soma and activates action potential-generating currents (I_{Na} and I_K), thus initiating the burst. Finally, the action potential propagates to the dendrite, producing a dendritic burst of smaller amplitude.

The model predicts that in synaptically isolated cells, the bursting mechanism depends on neuromodulators, endogenously released within the pBC. The neuromodulatory tone can bias the neuron to a somatic (I_{NaP}) or dendritic (Ca^{2+} and I_{CaN}) mode of bursting, or a hybrid of the two. In the dendritic mode, the period of bursting is largely modulated by the IP_3 concentration, whereas in the somatic mode the burst duration is modulated by the persistent sodium current. This model displays changes in burst duration and period that are consistent with experimentally published pharmacological manipulations, such as the application of ion channel blockers (FFA and Riluzole) as well as neuromodulatory manipulations.
