Congenital thrombophilia

COVID-19 infection

Venous thromboembolism risk

ABSTRACT

Background: Coagulation dysfunction represents a serious complication in patients during the COVID-19 infection, while fulminant thrombotic complications emerge as critical issues in individuals with severe COVID-19. In addition to a severe clinical presentation, comorbidities and age significantly contribute to the development of thrombotic complications in this disease. However, there is very little data on association of congenital thrombophilia and thrombotic events in the setting of COVID-19. Our study aimed to evaluate the risk of COVID-19 associated thrombosis in patients with congenital thrombophilia.

Methods: This prospective, case-control study included patients with confirmed COVID-19 infection, followed 6 months post-confirmation. The final outcome was a symptomatic thrombotic event. In total, 90 COVID-19 patients, 30 with known congenital thrombophilia and 60 patients without thrombophilia within the period July 2020–November 2021, were included in the study. Evaluation of hemostatic parameters including FVIII activity and D-dimer was performed for all patients at 1 month, 3 months and 6 months post-COVID-19 diagnosis.

Results: Symptomatic thrombotic events were observed in 7 out of 30 (23 %) COVID-19 patients with thrombophilia, and 12 out of 60 (20 %) without thrombophilia, $P = 0.715$. In addition, the two patient groups had comparable localization of thrombotic events, time to thrombotic event, effect of antithrombotic treatment and changes in FVIII activity, while D-dimer level were significantly increased in patients without thrombophilia.

Conclusion: Our findings suggest that patients with congenital thrombophilia, irrespective of their age, a mild clinical picture and absence of comorbidities, should receive anticoagulant prophylaxis, adjusted based on the specific genetic defect.

1. Introduction

Coagulation dysfunction represents a serious complication in patients with COVID-19 infection and can lead to fulminant thrombotic complications which adds to the morbidity in this patient population

[1]. Based on previous studies, several changes towards the prothrombotic phenotype can be explained by the profound inflammatory response, as well as by hypoxia [2–6]. Activation of the coagulation system caused by the presence of a novel coronavirus may result in numerous vascular complications such as venous thromboembolism

one patient from FV Leiden group was on long time VKA due to the recurrent thrombosis.

(VTE) and arterial thrombosis, with significant implications on the clinical outcome for COVID-19 patients [7]. Thromboembolism significantly increases the odds of mortality in COVID-19, being as high as 74 % [8]. It should be emphasized that the severity of the clinical picture, as well as comorbidities, significantly contribute to the development of thrombotic complications. In relation to the clinical presentation, many patients with acute respiratory distress syndrome (ARDS) secondary to COVID-19, develop life-threatening thrombotic complications despite anticoagulation [9]. Additionally, increasing age is associated with a higher prevalence of VTE and pulmonary embolism, while increased body-mass index was only shown to be associated with increased prevalence of pulmonary embolism [10].

Thrombophilia has been hypothesized to contribute to thrombotic risk, however this hypothesis is based almost entirely on individual case reports [11–13]. To date, the largest published cohort study included 13 patients with congenital thrombophilia, and the majority of patients with severe thrombophilia did not develop symptomatic thrombotic events during COVID-19, including those with previous thrombosis. A possible explanation for the low incidence of thrombosis in COVID-19 patients with thrombophilia may relate to the fact that these patients were in fact treated with anticoagulants prior to the infection, or at the very early stages of disease [14].

Our study aimed to primarily evaluate the risk of thrombosis among COVID-19 patients with known congenital thrombophilia, and to

compare their results to COVID-19 patients without thrombophilia. The secondary goal was to evaluate the effect of anticoagulant therapy in the prevention of thrombosis in these patients.

2. Materials and methods

Institutional approval for the study was granted by the Local Research Ethics Committee in accordance with the internationally accepted ethical standards. Each patient signed the informed consent form.

Patients with confirmed COVID-19 infection related to nasopharyngeal swab SARS-CoV-2 reverse transcriptase-polymerase chain reaction (RT-PCR) test were prospectively recruited and followed for 6 months post-COVID-19 infection. Inclusion criteria were: all patients older than 18 years of age, with known thrombophilia, who tested positive for SARS-CoV-2. Patients with COVID-19 infection without thrombophilia who were referred to the COVID hospital with symptoms of COVID infection, and who were confirmed positive for SARS-CoV-2 were included as a control group. The study took place in the period from July 2020 to November 2021. The data related to the period of hospitalization were obtained from the health information system of the Clinical Hospital Center “Bezanijska Kosa” (Heliant, v7.3, r48602) or from the patient discharge list and medical records. Participant data included demographic data: age, gender, BMI, comorbidities, previous

thrombosis, anticoagulant status prior to COVID-19 and during the COVID-19 treatment, as well as clinical presentation of COVID-19 infection.

Thrombotic events developed during the acute COVID-19 infection, or in the following next 6 months, were defined as COVID-19 related thrombosis. In all suspected thrombotic events color Doppler or computed tomography (CT scan) were performed with the results used for the differentiation of the type and location of thrombotic events.

During the follow-up period, the laboratory evaluation of hemostatic parameters included FVIII activity and D-dimer at 1 month, 3 months, and 6 months post-COVID-19 infection. Specifically, whole blood was collected into two Vacutainer citrate tubes (Vacutest; Kima, containing 1/10 volume sodium citrate stock solution at 0.129 mmol/L) using sterile, atraumatic venipuncture. Two samples were taken for each patient and prepared using the standard method to obtain platelet poor plasma, with aliquots stored at -80 °C until testing. Factor VIII:C was measured using the 1-stage clotting assay with IL test reagents (Instrumentation Laboratory, Milan, Italy), and analyses were performed using IL ACL 6000 coagulometers (Instrumental Laboratory Milano), with levels above 1.5 IU/mL considered as increased [15]. D-dimer was measured using the Innovance D-dimer (Siemens Healthcare Diagnostics), immunoturbidimetric assay for the quantitative determination of cross-linked fibrin degradation products (D-dimer) in human plasma using BCS Siemens coagulometer, with results expressed in mg/L FEU (fibrinogen equivalent units). The cut-off value used for discrimination of VTE was 0.5 mg/L FEU for patients under 50 years of age, while in patients older than 50 years of age adjusted D-dimer level was used.

Results of the hemostatic parameters and data related to patients with thrombophilia (genetic results and anamnestic data related to the thrombotic or anticoagulant status) were collected from the laboratory information system and thrombophilia registry.

2.1. Statistical analyses

Description of the data was performed using median and interquartile range (IQR) (for non-Gaussian data distribution) and mean and standard deviation (SD) (for Gaussian data distribution). Differences between groups were measured using the Mann-Whitney U test and Independent samples t-Test. Kaplan-Meier test was used for determination of time-to-thrombotic event estimation. Correlation between parameters was performed using the Spearman's rho test. The statistical analysis was performed using the Statistical Package for Social Sciences 21.0 for Windows (SPSS Inc., Chicago, Illinois, USA).

3. Results

3.1. Patients with congenital thrombophilia

Clinical and biological characteristics of 30 patients with COVID-19 and congenital thrombophilia are shown in Table 1, and included 8 patients with Antithrombin (AT) deficiency. The mutations on the SERPINC1 gene that cause two types of AT deficiency, were present in an equal number in the heterozygous variant, except for one carrier of the homozygous Type II HBS deficiency. Four patients had Protein S (PS) deficiency, with the diagnosis made on the basis of functional and antigenic PS assays, without the corresponding genetic results. The prothrombotic mutations on the F5 and F2 genes were noted in 18 patients, with 12 patients being carriers of the Factor V (FV) Leiden mutation (c.1601G > A p.R534Q), 2 of which were homozygous. Three patients were carriers of the c.*97G > A heterozygous prothrombin gene mutation, with a further two being carriers of the c.1787G>A (Belgrade mutation), with one patient being a carrier of both heterozygous prothrombotic mutations, while one a carrier of the AT deficiency Type I and FV Leiden mutation (c.548Cdel, p.Ser151(183)SerfsX100, heterozygous/c.1601G>A p.R534Q). In patients with congenital

F/M (female/male), BMI (body mass index-overweight BMI > 25), Obese BMI > 30, COVID (corona virus disease), AC status (anticoagulant status-use of AC drugs), m – month, FVIII (Factor VIII), FEU (fibrinogen equivalent units-0.5 mg/L cut-off value used for discrimination of VTE), m (month), UTE (unusual thrombosis), SD (standard deviation), IQR (interquartile range) * difference in relation to the respiratory support (3 patients with CT score 17 were on mechanical ventilation), difference between investigated groups in relation to the hemostatic parameters during 1 month #, 3 months & and 6 months ** of follow up.

Fig. 1. Time of VTE occurrence depending on thrombophilia presence.

thrombophilia 7 were asymptomatic carriers, while recurrent VTE was observed in 8 patients, all of whom were placed on long-term vitamin K antagonists (VKA).

3.2. Case-control analysis of patients with congenital thrombophilia

Clinical features of the 30 COVID-19 patients with thrombophilia and 60 patients without thrombophilia are shown in Table 2. The following parameters were significantly different between the two groups: age, comorbid diseases, previous thrombosis, the need for hospitalization, respiratory support and anticoagulant status prior to the COVID-19 infection. During the follow-up period, thrombotic events were observed in 7 out of 30 (23 %) patients with thrombophilia and 12 out of 60 (20 %) without thrombophilia, $P = 0.715$. A similar distribution of thrombosis location, time to thrombotic event, and changes in FVIII activity were observed across both groups, while, D-dimer was significantly higher in patients without thrombophilia. There was a significant correlation between the VTE occurrence and FVIII function across all measurements. When it comes to D-dimer, only the measurement at one month post infection showed significant correlation with VTE (Table 3, Supplemental Data).

Analysis of hemostatic parameters during the follow up shows that patients who developed thrombosis, regardless of the thrombophilia status, had a significantly higher level of FVIII compared to patients who did not develop thrombosis. In case of D-dimer, the difference was significant only at the 1 month post-infection (Table 4, Supplemental Data).

3.3. Use of antithrombotic therapy during COVID-19 infection

Eleven patients with thrombophilia and 8 without thrombophilia received oral anticoagulant therapy, which included VKA (8 with and one without thrombophilia), and DOAC (3 with thrombophilia and 5

without thrombophilia). Patients on VKA therapy were stable, with the INR level maintained in the range of 2 to 3. Patients receiving DOAC introduced during the COVID-19 infection, 8 patients received Rivaroxaban (20 mg per day), and two patients without thrombophilia received Apixaban (2×2.5 mg per day). From the group that was already on VKA treatment, one patient with AT deficiency developed acute deep vein thrombosis (DVT) on two occasions. The first event occurred during the acute infection, while the second recurrent event developed in the period two months after she become PCR negative for SARS-CoV-2.

Hospitalized patients with severe COVID-19 infection received a high prophylactic dose of Low Molecular Weight Heparin (LMWH), Enoxaparin 40 mg subcutaneously twice daily, while patients with non-severe disease received Enoxaparin 40 mg once daily. Eight patients with thrombophilia received Enoxaparin once daily, while 18 patients without thrombophilia received a high prophylactic dose of LMWH. Two patients (one patient with thrombophilia (carrier of FV Leiden mutation) and one without thrombophilia) received only one week of Enoxaparin prophylaxis, and developed thrombotic events post-COVID-19 infection. There were 3 patients without thrombophilia who presented with severe COVID-19 and who required respiratory support, that had thrombotic events within 1 to 3 months post interruption of anticoagulant therapy.

An equal number patients from both groups with a mild clinical picture received 100 mg Aspirin for one month post COVID-19 diagnosis, with one patient with thrombophilia (carrier of the FV Leiden mutation) developing a thrombotic event 5 months post-COVID-19 diagnosis.

There were 30 young patients with a mild clinical picture (4 with thrombophilia and 26 without thrombophilia) that did not receive prophylaxis. Thrombotic events developed in 3 patients with thrombophilia during acute infection (one patient with heterozygous AT deficiency type II HBS and one patient with heterozygous FV Leiden mutation). Both of these patients developed distal vein thrombosis,

while the carrier of prothrombin mutation developed abdominal thrombosis (*v. portae*) 3 months post-COVID-19 infection. Eight patients without thrombophilia developed thrombosis, one during acute infection and 7 at 1 month to 4 months post-infection.

The timing of thrombotic events in relation to the COVID-19 infection across the entire cohort is shown in Fig. 1, showing that presence of thrombophilia did not have an effect on the timing of the thrombotic event, $P = 0.819$.

4. Discussion

To our knowledge, this is the largest case-control study of patients with congenital thrombophilia infected with SARS-CoV-2. The main finding was that there was an equal incidence of thrombotic events among patients with congenital thrombophilia and those without thrombophilia related to COVID-19, with the risk for VTE being present several months post SARS-CoV-2 infection. Our results confirm previous findings that low incidence of thrombosis in thrombophilia patients may be related to the fact that these patients were already treated with anticoagulants prior to the COVID-19 infection [14]. Another important reason for a comparable incidence of thrombotic events associated with COVID-19 could be linked to the younger age, a mild clinical picture and lower incidence of comorbidities in the thrombophilia group. Contrary to this, in the group without thrombophilia there was a high number of patients with comorbidities including cardiac disease, diabetes and hypothyroidism, that could significantly affect the development of a more severe clinical presentation. The fact that two patients without thrombophilia developed thrombosis one month post discharge is in accordance with previously published study describing high incidence of thrombosis in patients with severe clinical presentation [1].

According to existing guidelines, the use of LMWH is recommended for prophylaxis or treatment COVID-19 induced thrombosis [16–18], and 57 % of our patients (27 % with thrombophilia and 30 % without thrombophilia) were in fact receiving LMWH. The prophylaxis was introduced based on risk stratification and published recommendations [16] during admission to the COVID hospital, except for those who were already receiving VKA and, as expected there was a low incidence of thrombosis was observed in these patients, regardless of the thrombophilia status.

On the other hand, the majority of young patients who had a mild clinical picture received Aspirin and did not have thrombotic complications, while the remainder did not receive any antithrombotic therapy, as per recommendations. In the latter patient group, an equally high number of patients developed thrombosis, independent of the thrombophilia status.

Considering that FVIII is an acute phase reactant, there is debate as to whether increased FVIII levels in represent an increased inflammatory state [19]. We observed significantly higher FVIII levels in patients who developed thrombosis, compared to those without thrombosis. An increase in FVIII could in fact suggest hypercoagulability in patients post-COVID-19, supported by increase across both patient populations. Our results suggest that monitoring of FVIII levels could be a useful tool in assessing hypercoagulability and possible thrombotic risk, especially in patients with known thrombotic risk factors. Previous studies have shown that patients admitted to intensive care, or those with severe COVID-19 requiring respiratory support, had increased FVIII levels during the acute infection [20–23]. In addition, hospitalized COVID-19 patients with increased FVIII levels, maintained a significantly higher FVIII level, compared to healthy controls 4 months post-discharge [24].

Our results related to asymptomatic young carriers of thrombophilia presenting with non-severe COVID-19 infection, who have not received any antithrombotic therapy, is consistent with recent findings of Mahmoud et al. Namely, the authors emphasize that inherited thrombophilia with endotheliopathy appears to be a plausible mechanism for thrombosis in a proportion of noncritical patients with COVID-19, without association with COVID-19 severity [25]. With this in mind, it is

important that all patients with congenital thrombophilia, regardless of age, a mild clinical picture or absence of comorbidities, receive adequate prophylaxis. The type and duration of anticoagulation therapy and secondary thromboprophylaxis should be adjusted based on the specific genetic defect that causes thrombophilia. When analyzing thrombotic events in relation to the type of thrombophilia and applied prophylaxis, AT deficiency is the most severe thrombophilia in the setting of COVID-19. In patients with homozygous antithrombin Type II HBS deficiency, the risk for VTE is particularly pronounced, even in the presence of mild clinical COVID infection and absence of comorbidities [11].

The main limitation of our study is small sample size, in addition to the selection bias present due to the significant difference between investigated and control group in relation to comorbidities and clinical presentation of COVID-19 infection, as a possible risk factor for development of COVID-19 related thrombosis. Despite limitations, our study is the first prospective study representing valuable data related to thrombophilia in the setting of COVID-19 infection.

5. Conclusion

Our study showed an equal incidence of thrombotic events among patients with congenital thrombophilia and those without thrombophilia in the setting of COVID-19, and that the risk for VTE may be present for several months post-COVID-19 infection. Patients with congenital thrombophilia, regardless of the age, and in the setting of a mild clinical picture or absence of comorbidities, should receive anticoagulant prophylaxis adjusted for the specific genetic defect. Patients with homozygous AT deficiency Type II HBS were among those with the highest risk for thrombosis related to COVID-19 infection.
