Abstract. To evaluate the impact of dietary vitamin E supplementation on growth performance, the intestinal structure and function of channel catfish (*Ictalurus punctatus*, Rafinesque 1818) was investigated. A total of 900 healthy channel catfish (weight, 5.20 ± 0.15 g) were divided into four groups, which received experimental diets with different vitamin E content (0, 50, 100 or 1,000 mg/kg). At the end of the feeding trial (after 15 weeks), the growth and gut performance of the animals was determined. The digestive enzyme activity in hepatopancreas and gut was also detected. In addition, the height of intestinal fold, the thickness of the mucous membrane and the number of somatostatin-positive cells was examined by histological analysis. Dietary vitamin E supplementation at 50 and 100 mg/kg significantly improved the growth and gut performance, which also increased the activity of several digestive enzymes compared to that in animals without vitamin E supplementation ($P < 0.05$). In addition, vitamin E supplementation also significantly increased the height of intestinal fold and the thickness of the mucous membrane ($P < 0.05$). Fish with dietary vitamin E supplementation at appropriate doses also had more somatostatin-positive cells in than those without vitamin E supplementation ($P < 0.05$). In conclusion, dietary vitamin E supplementation at 50 and 100 mg/kg was shown to improve the growth performance as well as intestinal structure and function of channel catfish.

Introduction

Vitamin E is a generic term for all naturally occurring tocopherols and tocotrienol as well as their derivatives (1). This fat-soluble vitamin was discovered and named by Evans in the 1920s (2,3). Since its hydroxyl moiety on carbon 6 can be easily oxidized, vitamin E has a strong reducibility, which protects important substances from oxidation *in vivo* and has an important role in the maintenance of normal metabolic processes and physiological function in the body (4). Vitamin E is required to protect the cell membrane from peroxide damage, maintain immunity and enhance resistance to disease, whilst it is tightly associated with embryonic development, nucleic acid metabolism, ascorbic acid biosynthesis as well as maintenance of tissue quality (5-9). Vitamin E has become one of the most important vitamins in aquatic animal breeding. A large number of studies have reported that vitamin E deficiency impairs aquatic animal performance, including a reduced weight gain, protein efficiency ratio as well as feed coefficient (10-15).

The channel catfish (*Ictalurus punctatus*, Rafinesque 1818) is well known for its meat that is tasty and high in amino acids. It is naturally distributed within the USA and Canada and has been widely introduced to other countries worldwide due to its value (16). This fish has become one of the most economically important fish in China. Channel catfish require relatively high levels of vitamin E and its deficiency significantly inhibits fish growth (17). The intestine is a major organ for energy and nutrition absorption to maintain survival, growth and reproduction of fish. Although several studies have investigated the effects of vitamin E on weight gain, tissue ascorbate concentration as well as stress responses (18-20), few studies have investigated the effects of vitamin E on the intestinal structure and function.

The first purpose of the present study was to investigate the effect of vitamin E supplementation on growth performance and to determine the optimum dietary vitamin E supplementation level for channel catfish. The second purpose of the study was to explore the effects of vitamin E supplementation on the intestinal structure and function of channel catfish. In addition, the present study assessed the effects of vitamin E supplementation on the expression of somatostatin, which is

distributed in the gastrointestinal tract and acts as a hormone as well as a neurotransmitter to regulate a variety of physiological processes, such as the body's growth, development and metabolism (21-23). The present study provided a scientific reference for the breeding of channel catfish.

Materials and methods

Experimental diets. All experimental protocols were approved by the University of Sichuan Agricultural Animal Care Advisory Committee (Ya'an, China). The experimental diets were varied with regard to the level of vitamin E. The basal diet (Table I) was formulated according to the Nutrient Requirements of Fish from the NRC National Research Council (24) and was supplemented with 0, 50, 100 or 1,000 mg/kg DL-all-rac- α -tocopherol acetate (Sanyou Institute of Special Additives, Chengdu, China). A study utilizing the dose of 1,000 mg/kg has been described previously (25). For diet preparation, the ingredients were ground into fine powder and screened through a mesh (0.38 mm). All ingredients were then thoroughly mixed and made into a 4 mm-diameter soft pellet diet using a pellet feed mill. After natural air drying in the dark, the pellets were preserved in a freezer at -20°C . In addition, to assess the proximate composition of the diets, crude protein, crude fat and energy were determined using a Kjeldahl apparatus (nitrogen $\times 6.25$; Xi'an HEB Biotechnology Co., Ltd., Xi'an, China), extraction with petroleum ether by a Soxhlet apparatus (Xi'an HEB Biotechnology Co., Ltd.) followed by ash incineration at 600°C for 3 h and bomb calorimetry, respectively. The composition of the catfish's diet is shown in Table I.

Experimental animals. A total of 900 healthy channel catfish (*Ictalurus punctatus*, Rafinesque 1818; weight, 5.20 ± 0.15 g; age, 2 years old) were purchased from a fish farm (Sichuan Fisheries Science and Technology Development Co., Ltd., Xinjin, China), where they were originally hatched and reared. They were randomly divided into four groups (225 fish per group) according to the vitamin E content in the experimental diet. For each group, fish were equally divided among three circular tanks with a volume of 20 l (total number of tanks, 12), leading to a density of 75 fish per tank.

Prior to starting the feeding trial, fish were acclimatized for two weeks on a basal diet that was not supplemented with vitamin E and then fed one of the four experimental diets by hand three times daily (07:30, 13:30 and 19:30 h) to approximate satiation for 15 weeks based on percentage body weight. Feed consumption was monitored at each feeding. The feeding rate was adjusted once or twice a week based on the feeding activity of fish. The tanks were configured as a flow-through culture system and the incoming water was filtered with aeration. The average water temperature was $21 \pm 2^{\circ}\text{C}$ with a pH of 6.8-7.5, and the amount of dissolved oxygen was 8-10 mg/l. Fish were reared in a 12 h light/dark cycle.

Growth performance. All of the fish in each tank were counted and weighed to monitor growth rates at the end of the feeding trial. The parameters indicating the growth performance of catfish in each group, including average weight gain, average daily growth, feed coefficient and protein efficiency ratio,

were calculated following standard protocols. The formulas were as follows: i) Average weight gain (g/fish) = average final weight (g) - average initial weight (g); ii) Average daily growth (g/fish/day) = average weight gain (g/fish)/duration of experiment (days); iii) Protein efficiency ratio = wet weight gain (g)/protein intake (g); iv) Feed coefficient (%) = dry feed fed (g)/wet weight gain (g); and v) Survival (%) = (final number of fish/initial number of fish) $\times 100\%$.

Analysis of digestive enzyme in hepatopancreas and gut. After recording of body measurements, 45 fish were collected from each group. The hepatopancreas and gut of fish were removed, frozen in liquid nitrogen and then preserved at -80°C for further analysis. For digestive enzyme analyses, tissue samples were homogenized in ice-cold physiological saline and the supernatant was retained after centrifugation at $3,200 \times g$ for 20 min. The activities of lipase were evaluated using phenolphthalein indicator and the activities of protease were determined by the Folin-phenol reagent method. In addition, the alkaline phosphatase (AKP) assay kit (Nanjing Jiancheng, Nanjing, Jiangsu, China) were used to evaluate the AKP activities, and Na^+/K^+ -ATPase activities were assessed using a Na^+/K^+ -ATPase assay kit (Nanjing Jiancheng, Nanjing, China).

Values are expressed as the mean ± standard deviation. ^aP<0.05, compared to the group receiving 0 mg/kg vitamin E; ^bP<0.05, compared to the group receiving 1,000 mg/kg vitamin E.

Gut performance. Another 45 fish collected from each group at the end of the feeding trial were dissected and the guts were removed. The gut weight and length of the fish from each group was recorded. Moreover, the gut weight index and gut length index were calculated as follows: i) Gut weight index (%) = [average gut weight (g)/average final body weight (g)] x 100%; and ii) Gut length index (%) = [average gut length (cm)/average final body length (cm)] x 100%.

Histological analysis. After recording of body measurements, another 20 fish were collected from each group and 0.5 cm of each segment of intestine was sampled on a chilled cutting board according to a previous description (26). Samples were fixed in Bouin solution for 12 h, embedded in paraffin (Sigma-Aldrich, Merck KGaA, Darmstadt, Germany) and cut into 5- μ m sections using a Leica RM2128 microtome (Leica Microsystems, Wetzlar, Germany). A proportion of the sections from each segment of the intestine was stained with hematoxylin and eosin (H&E) and observed under an Olympus BH-2 microscope (Olympus, Tokyo, Japan). The height of intestinal folds and the thickness of the mucous membrane were evaluated by analyzing more than ten different views of each sample of intestine segment using Spot software (Version 4.0.6; Diagnostic Instruments, Sterling Heights, MI, USA).

The other part of the tissue sections was used for immunohistochemical analysis for detecting the distribution and expression of somatostatin. After washing with PBS three times, sections were rehydrated and incubated in 3% H₂O₂ for 10 min. Subsequently, sections were incubated with rabbit anti-somatostatin primary antibody (BA0124; Wuhan Boster Biological Technology, Ltd, Wuhan, Hubei, China) at a dilution of 1:100 at 4°C for 17 h, followed by incubation with the biotin-conjugated goat anti-rabbit secondary antibody (BA1003; Wuhan Boster Biological Technology, Ltd, Wuhan, Hubei, China). Finally, sections were stained using a Streptavidin-Biotin Peroxidase Complex kit (Wuhan Boster Biological Technology, Ltd, Wuhan, Hubei, China) and visualized using diaminobenzidine as a chromogen. Sections incubated with PBS instead of primary antibody

were considered as a negative control. The slices were observed and images were captured using a digital camera (Moticam 2500, Motic, Hong Kong, China) attached to a Nikon microscope (Nikon Eclipse 50i, Nikon, Tokyo, Japan). The expression of somatostatin among groups was evaluated by determining the number of somatostatin-positive cells. Ten different views per section of each segment of intestine (three sections for each segment intestine from each group) were obtained to analyze the expression and distribution of somatostatin.

Statistical analysis. Values are expressed as the mean ± standard deviation. Significant differences among groups were determined by one-way analysis of variance followed by Duncan's method. P<0.05 was considered to indicate a statistically significant difference between groups. All statistical analyses were performed with SPSS 19.0 software (International Business Machines, Inc., Armonk, NY, USA).

Results

Effect of vitamin E supplementation on the growth performance of channel catfish. Average weight gain, protein efficiency ratio, feed coefficient as well as survival were calculated and presented in Table II. Dietary supplementation with vitamin E affected catfish survival and fish with vitamin E supplementation at different concentrations showed a higher survival rate than those without. In addition, the fish receiving diets supplemented with vitamin E had significantly higher growth parameters, including average weight gain, average daily growth as well as protein efficiency ratio than those fed with the basal diet (P<0.05) and the highest values occurred in fish receiving a diet supplemented with vitamin E at 100 mg/kg. The feed coefficient is used to evaluate the feed quality with a lower the feed coefficient indicating a higher feed quality. As shown in Table II, dietary supplementation with 50 and 100 mg/kg vitamin E had an obviously lower feed coefficient than that with 1,000 mg/kg vitamin E or without vitamin E (P<0.05).

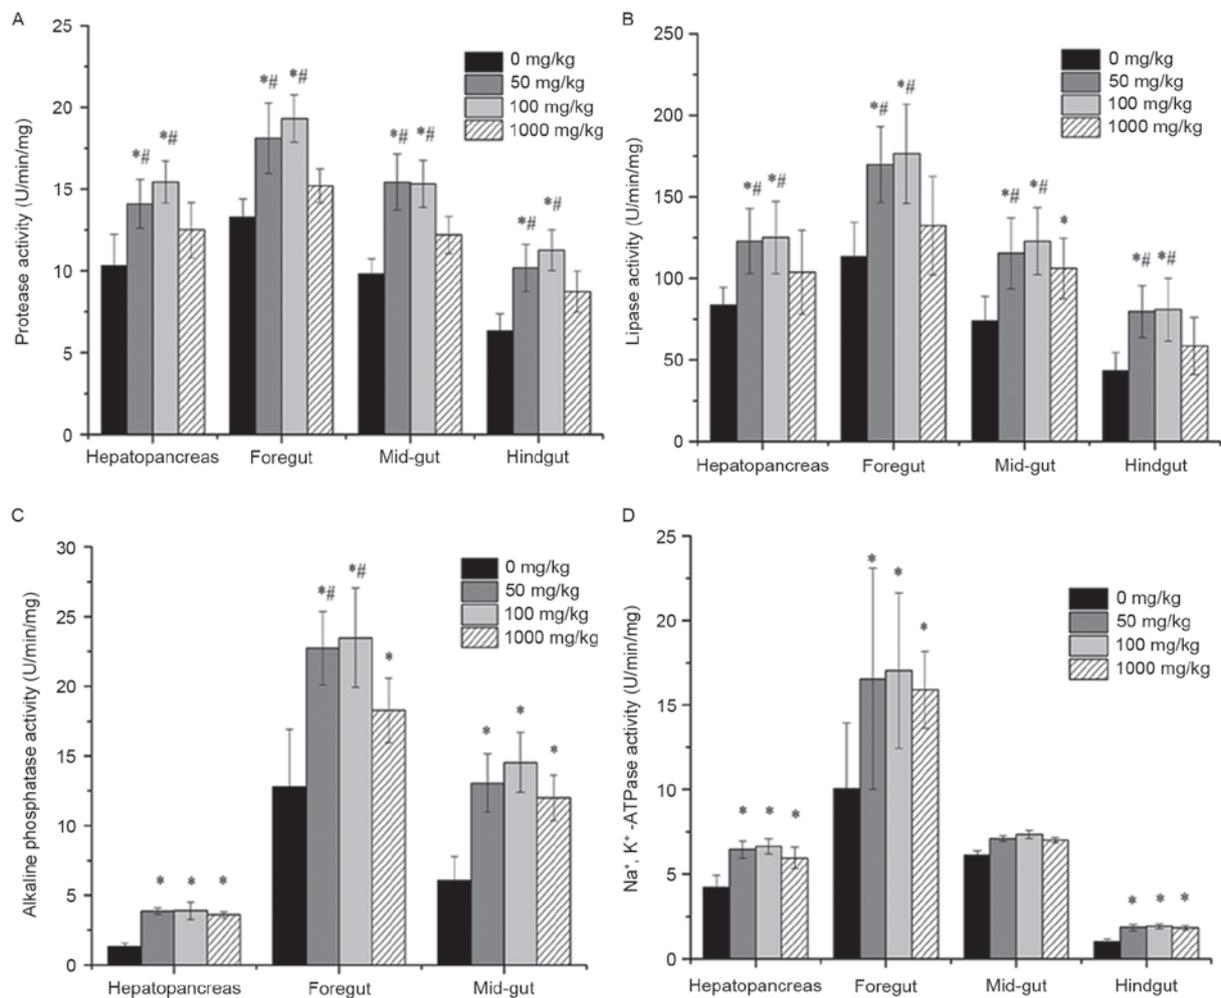

Figure 1. Digestive activity in the hepatopancreas and each segment of the gut of fish fed a diet supplemented with vitamin E: (A) Protease activity, (B) lipase activity, (C) alkaline phosphatase activity and (D) Na⁺/K⁺-ATPase activity. Values are expressed as the mean \pm standard deviation. *P<0.05, compared to the group receiving 0 mg/kg; #P<0.05 compared to the group receiving 1,000 mg/kg.

Effects of vitamin E supplementation on digestive enzyme activity in channel catfish. Digestive enzyme activity in the hepatopancreas and each gut segment of fish supplemented with different concentrations of vitamin E was shown in Fig. 1. In the hepatopancreas and all segments of the fish gut for 50 and 100 mg/kg vitamin E groups, protease activity was significantly increased compared to that without vitamin E supplementation (P<0.05) and that in 1,000 mg/kg group (P<0.05). However, there was no significant difference in the 1,000 mg/kg group compared with that of the 0 mg/kg group. Similarly, in the hepatopancreas and all segments of the fish gut for 50 and 100 mg/kg groups, lipase activity was significantly increased compared to that without vitamin E supplementation (P<0.05) and that in 1,000 mg/kg group (P<0.05). Additionally, there was no significant difference in the hepatopancreas, foregut and hindgut of fish in 1,000 mg/kg group compared with the 0 mg/kg group, except in the mid-gut (P<0.05). AKP activity was significantly increased in the hepatopancreas, foregut and mid-gut of fish in 50, 100 and 1,000 mg/kg groups compared to that without vitamin E supplementation (P<0.05). Na⁺/K⁺-ATPase activity was significantly increased in the hepatopancreas, foregut and hindgut of fish in 50, 100 and 1,000 mg/kg groups compared

to that without vitamin E supplementation (P<0.05). However, there was no significant difference in the mid-gut of fish in 50, 100 and 1,000 mg/kg groups compared with the 0 mg/kg group (P>0.05). In addition, the concentration of supplemented vitamin E influenced the digestive enzymes activity, since fish supplemented with vitamin E at 50 and 100 mg/kg showed obviously higher activities of protease, lipase and AKP than that without vitamin E (P<0.05). Although the fish in 1,000 mg/kg group also exhibited increased activities, the values were lower than those in the 50 and 100 mg/kg groups.

Effects of vitamin E supplementation on gut performance of channel catfish. The results of gut weight, gut weight index, gut length as well as gut length index of fish supplemented with different concentrations of vitamin E are shown in Table III. Fish fed diets supplemented with vitamin E had a greater gut length and gut weight compared to those without (P<0.05). The gut weight index and gut length index of fish with vitamin E supplementation were also markedly higher than those of fish without vitamin E supplementation (P<0.05).

Effects of vitamin E supplementation on the height of intestinal folds and the thickness of the mucous membrane. The

Values are expressed as the mean ± standard deviation. ^aP<0.05, compared to the group receiving 0 mg/kg vitamin E.

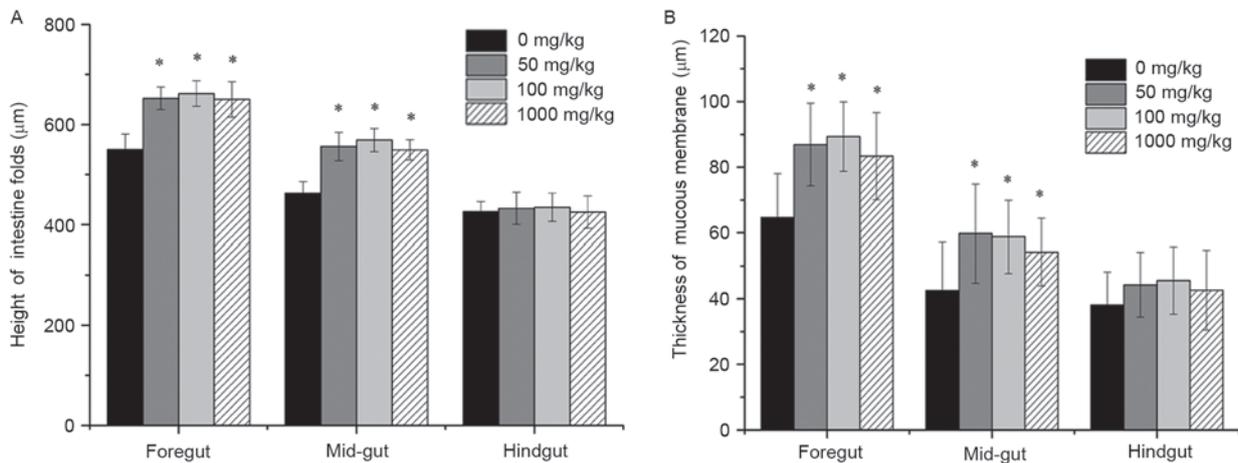

Figure 2. (A) Intestinal fold height and (B) mucous membrane thickness in each segment of gut of fish fed a diet supplemented with vitamin E. Values are expressed as the mean ± standard deviation. *P<0.05 compared to the group receiving 0 mg/kg.

intestinal fold height and of mucous membrane thickness were observed under a microscope after H&E staining and the statistical results are shown in Figs. 2 and 3. The intestinal folds in fish fed a diet without vitamin E showed an irregular morphology and they were small, thin and loosely arranged throughout, while they were much larger and more tightly arranged in fish fed a diet supplemented with vitamin E. Statistical analysis indicated that fish fed diets containing vitamin E had significantly larger intestinal fold height as well as a thicker mucous membrane (P<0.05).

Effects of vitamin E supplementation on the distribution and expression of somatostatin. Somatostatin-positive cells were observed in the foregut, mid-gut as well as hindgut. The distribution of somatostatin-positive cells in the foregut of fish fed a diet supplemented with different amounts of vitamin E is shown in Fig. 4A-D. Somatostatin-positive cells (brown-yellow granules) with various cellular morphologies were mainly located at the bottom of the intestinal epithelial cell layer and some of them were found between cells of the mucous epithelium. The distribution of somatostatin-positive cells among the groups in the mid- and hindgut was similar to that in the foregut (data not shown). In addition, the expression of somatostatin was evaluated by quantifying the number of somatostatin-positive cells in ten different views per section and

the results for each segment of the intestine are shown in Fig. 4E. The number of somatostatin-positive cells was significantly higher in the foregut of fish with vitamin E supplementation at different concentrations compared with that in the foregut of fish without supplementation (P<0.05). Moreover, dietary supplementation of vitamin E at 100 and 50 mg/kg resulted in an obviously larger number of somatostatin-positive cells in the foregut and mid-gut of fish than that at 1,000 mg/kg (P<0.05).

Discussion

The present study was performed based on a dose response design. The results indicated that the weight gain, survival rate and protein efficiency ratio of fish increased with dietary vitamin E supplementation at increasing doses of up to 100 mg/kg, after which a further increase did not achieve any improvements or had a less pronounced effect. This trend was similar to that previously described in other animals (27). These results suggested that dietary supplementation with vitamin E is beneficial for the growth of catfish. A large body of evidence has indicated that vitamin E at a certain dose range promoted the growth of aquatic animals (28). Vitamin E deficiency induces excessive production of toxic lipid peroxides, leading to a decrease of weight gain and feed efficiency in animals. The addition of vitamin E to their diet

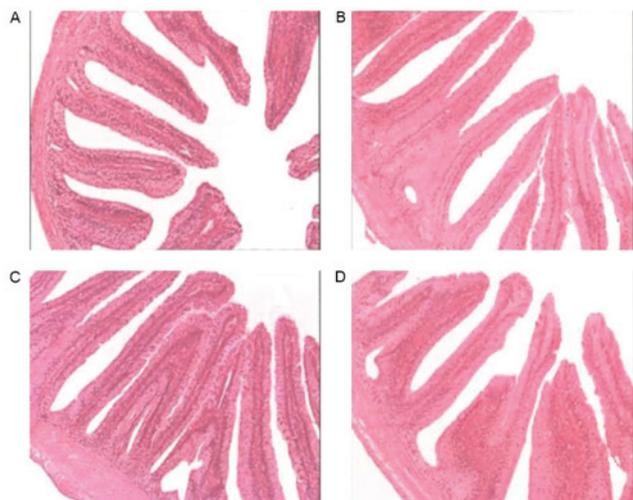

Figure 3. Morphology of intestinal folds in the foregut of fish fed a diet supplemented with vitamin E at (A) 0, (B) 50, (C) 100 and (D) 1,000 mg/kg assessed by hematoxylin and eosin staining (original magnification, x100).

prevents variable unsaturated fatty acids in diets and tissues of aquatic animals from oxidative rancidity and maintains a normal metabolism, thus increasing the survival rate, weight gain as well as feed efficiency of animals (29). In addition, dietary vitamin E supplementation decreased the feed coefficient in the present study, which has been an important and visual index to evaluate the feed quality. As previously described, adding an appropriate dose of vitamin E reduced the feed coefficient and increased the feed quality and feed efficiency (13,14), and the results of the present study were consistent with this.

It is well accepted that the intestine has an important role as the site of nutrient digestion and absorption, and digestive function correlates with the development of the intestinal tract. In the present study, intestine weight and length, which reflect the development of the intestine, were significantly increased in response to high dietary vitamin E. In addition, differences in gut length and weight among fish species appear to be associated with their feeding habits as described previously (30). In the present study, dietary vitamin E at a certain dose range promoted gut development. Aquatic animals have a relatively simple mucosal structure. Instead of the intestinal villus as in terrestrial animals, the intestinal fold directly reflects the digestive and absorptive ability of fish (31,32). Intestinal fold height has been considered as an indicator of the absorptive ability of aquatic animals. Moreover, the thickness of the mucous membrane correlates to the functional area of the intestine, directly influencing the absorption and transportation of nutrition. According to the results of the present study, dietary vitamin E at a certain dose range significantly increased the intestinal height and the thickness of the mucous membrane, thus improving the intestine function in catfish.

The ability of digestion is associated with the activity of digestive enzymes, which are affected by dietary intake (33,34). In the present study, dietary vitamin E at a certain dose range increased the activities of protease and lipase. Intestinal AKP is a marker enzyme in the intestinal mucosa, which reflects epithelial cell proliferation and absorptive ability of the intestine (35). In addition, this enzyme also correlates with

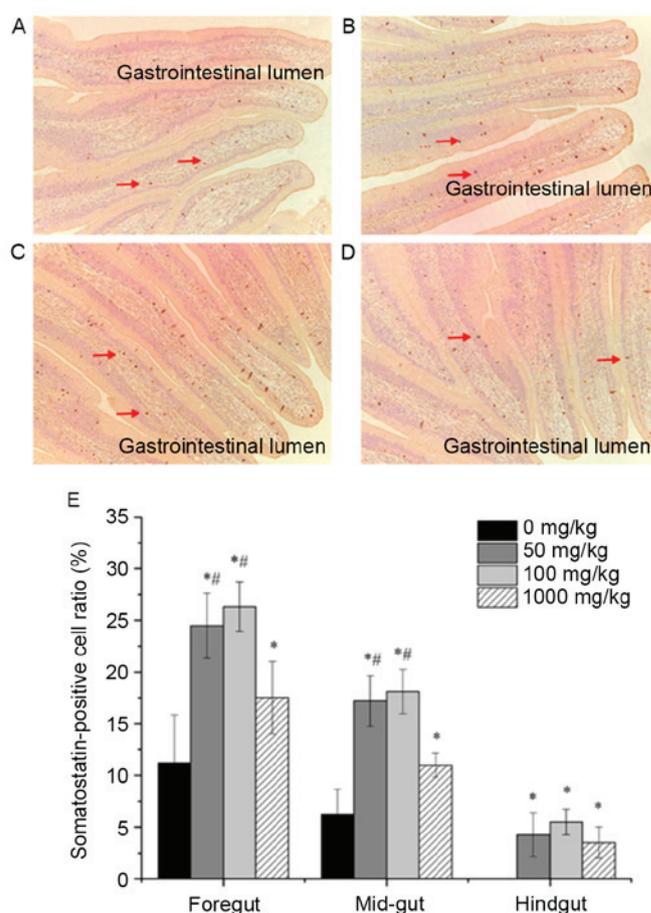

Figure 4. Distribution of somatostatin-positive cells in the foregut of fish fed a diet supplemented with vitamin E at (A) 0, (B) 50, (C) 100 and (D) 1,000 mg/kg was assessed by immunohistochemistry (original magnification, x100). Arrows indicate somatostatin-positive cells. (E) The amount of somatostatin-positive cells in each gut segment in each group. Cells were quantified in ten fields of view for each specimen. Values are expressed as the mean \pm standard deviation. * $P < 0.05$, compared to the group receiving 0 mg/kg; # $P < 0.05$, compared to the group receiving 1,000 mg/kg.

the degree of differentiation of enterocytes and its content reflects their maturation status (36). In the present study, the activity of AKP was observed only in the foregut and mid-gut and was significantly higher in fish with vitamin E dietary supplementation (at a certain range dose) than in those without. In addition, the absorption of certain nutrients, including amino acids and glucose, was associated with the absorption of Na^+ by Na^+/K^+ -ATPase. The activity of Na^+/K^+ -ATPase indirectly reflects the cell energy metabolism and function of the gut (37). As shown in the present study, vitamin E dietary supplementation at a certain dose range also increased the activity of this enzyme. Considering all of the above results, it is concluded that vitamin E dietary supplementation at a certain dose range significantly improved intestinal function. Furthermore, vitamin E had a stimulatory effect on digestion enzyme activity in the hepatopancreas of catfish. As previously reported, enzyme secretion is closely associated with the development of the hepatopancreas (38). Dietary supplementation of vitamin E also promoted the development of the hepatopancreas.

Somatostatin is a typical brain-gut peptide of dual distribution (21,39). Somatostatin protects epithelial cells in the digestive

tract from damage and necrosis caused by a variety of harmful substances (40). The distribution of somatostatin-positive cells in the gastrointestinal tract varied in different fish. For instance, in Korean aucha perch (*Coreoperca herzi*), *Monopterus albus* and *Perca fluviatilis*, somatostatin-expressing cells were only found in the stomach (41,42). In *Tilapia nilotica*, oriental sheatfish (*Silurus asotus*) and mandarin fish (*Siniperca chuatsi*), somatostatin-expressing cells were found in the stomach and intestines (42). In the present study, somatostatin-expressing cells existed only in the intestines of channel catfish rather than in the stomach. However, channel catfish have more than two genes encoding different forms of somatostatin (43,44). Different endogenous somatostatin isoforms are already known to function differently not only between tissues but also within the same target cell/tissue in the same teleost species (45,46). Accordingly, further investigation of the distribution of somatostatin isoforms should also be performed. Due to the important role of somatostatin in the digestive tract, the expression of this protein may be regarded as another index to express the effects of vitamin E on gut function in channel catfish. According to the results of the present study, dietary supplementation of vitamin E at a certain dose range significantly increased the expression of somatostatin.

In conclusion, dietary vitamin E supplementation at doses within a certain range promote the growth of channel catfish and improve their intestinal structure and function. The optimal dietary vitamin E supplementation should be limited to the range of 50-100 mg/kg. Due to the feasibility and efficacy of oral vitamin E supplementation for channel catfish, the present study provided an experimental foundation for the use of vitamin E for breeding of channel catfish in the aquaculture industry.
