Visual Abstract

Significance Statement

We describe a novel neural manipulation method using laser and liposomal nanostructures. The method enables us to release various types of neurochemicals and drugs in the mouse brain, beyond the range used by existing optical manipulation methods, such as optogenetics and caged compounds. We also demonstrate repeated and stable neural manipulation modulated by laser intensity. Given the established biocompatibility and stability of liposomes in the body, these findings suggest that the liposomal neural manipulation methods would be a useful tool for neuroscience research and further treatment of neurological disorders.

External control over rapid and precise release of chemicals in the brain potentially provides a powerful interface with neural activity. Optical manipulation techniques, such as optogenetics and caged compounds, enable remote control of neural activity and behavior with fine spatiotemporal resolution. However, these methods are limited to chemicals that are naturally present in the brain or chemically suitable for caging. Here, we demonstrate the ability to interface with neural functioning via a wide range of neurochemicals released by stimulating loaded liposomal nanostructures with femtosecond lasers. Using a commercial two-photon microscope, we released inhibitory or excitatory neurochemicals to evoke subthreshold and suprathreshold changes in membrane potential in a live mouse brain slice. The responses were repeatable and could be controlled by adjusting laser stimulation characteristics. We also demonstrate the release of a wider range of chemicals—which previously were impossible to release by optogenetics or uncaging—including synthetic analogs of naturally occurring neurochemicals. In particular, we demonstrate the release of a synthetic receptor-specific agonist that exerts physiological effects on long-term synaptic plasticity. Further, we show that the loaded liposomal nanostructures remain functional for weeks in a live mouse. In conclusion, we demonstrate new techniques capable of interfacing with live neurons, and extendable to *in vivo* applications.

Key words: femtosecond; laser; liposome; nanoshell; neurotransmitter; release

Introduction

The development of optical methods for manipulating neurons has revolutionized the investigation of causal relationships between neural activity and function, with the potential to add to the understanding of mechanisms and the treatment of neurological disorders. A particular strength of optical methods is the ability to interact with neurons with fine spatiotemporal resolution (Callaway and Yuste, 2002; Szobota and Isacoff, 2010; Shepherd, 2012; Lim et al., 2013), but existing methods have some important limitations. Until now, caged compounds and optogenetic methods have been the principal methods of optical manipulation. Caged compounds are made by bonding caging moieties with target chemicals, such as calcium, glutamate (Glu), and dopamine (Ellis-Davies, 2007). When optically stimulated, the caged compounds undergo photolysis and release the target chemicals. Uncaging techniques, however, are limited in the range of compounds that can be caged and may require complex synthesis procedures. In addition, they are limited to “one-shot” nonrepeatable release from each caged molecule. The more recent optogenetic method allows optical manipulation of neurons that are genetically modified to express light-activated protein (Papagiakoumou et al., 2010; Yizhar et al., 2011). Optogenetic stimulation can both activate and inhibit neurons, and, thus, can control

neurotransmitter release from neurons. However, optogenetic stimulation is limited to releasing neurotransmitters that are naturally synthesized by genetically targeted neurons. Due to these limitations, no existing method can stimulate the release of arbitrarily selected neurochemicals and drugs with amplitude controlled locally, repeatedly, and rapidly. We here report a new optical method enabling the use of a more complete pharmacopoeia of neurochemicals and drugs to specifically stimulate or inhibit particular receptors or ion channels, with high spatiotemporal resolution and repeatability.

In previous work, a new method of chemical release from liposomal nanostructures using optical stimulation was described (Wu et al., 2008; Leung and Romanowski, 2012; Nakano et al., 2014; Huang et al., 2015). Liposomal nanostructures are submicron spherical capsules comprising a lipid bilayer shell and an interior space that can be loaded with drugs. By tethering a gold nanoparticle to the liposome wall, the repeatable release of the encapsulated drug from the liposome can be effected by exposure to femtosecond laser pulses (Nakano et al., 2014). By adjusting laser stimulation parameters, the amount and speed of release can be controlled. In addition to the biocompatibility and capability to encapsulate many types of chemicals, this method has the favorable characteristic of providing rapid, on-demand, and repeatable delivery on a physiological timescale. Although these “in-beaker” results indicate the potential of this method for the manipulation of neural activity in neuroscience research, until now it has not been applied in living brain tissue.

In this study, we demonstrate experimental manipulation of neural activity in live mouse brain tissue by laser-stimulated release of neurochemicals from liposomal nanostructures, releasing a range of different neurochemicals, drugs, and metal ions. We also show that the amount of release from liposomes can be controlled, and that the release is repeatable and reliable. Importantly, we demonstrate the release of a wider range of chemicals than is possible using optogenetics or uncaging. In particular, we show that the release of a pharmacological agent, a synthetic receptor-specific agonist, could exert physiological effects on long-term synaptic plasticity.

These experiments demonstrate new possibilities for neural manipulation based on liposomal nanostructures.

Materials and Methods

Slice preparation

Animals were handled in accordance with protocols approved by the animal care and use committee of authors' university. Experiments were performed on male *Drd1a-eGFP* BAC transgenic mice bred on a Swiss Webster background (inbred; The Jackson Laboratory) and a C57BL/6 cross [age, postnatal day 30 (P30) to P80]. Animals were deeply anesthetized with isoflurane and decapitated, and the brain was removed rapidly. Horizontal slices, 300 μm thick, containing the hippocampus and entorhinal cortex or oblique horizontal corticostriatal slices were cut on a vibratome (VT1200S, Leica Microsystems) in a cold cutting solution containing the following (in mM): 92.0 *N*-methyl-D-glucamine, 2.5 KCl, 10.0 MgCl_2 , 0.5 CaCl_2 , 1.25 NaH_2PO_4 , 30.0 NaHCO_3 , 20.0 HEPES, 2.0 thiourea, 5.0 sodium ascorbate, 3.0 sodium pyruvate, and 25.0 glucose, and saturated with 95% O_2 /5% CO_2 (VT1200S, Leica). Slices were then incubated in oxygenated artificial CSF (ACSF) maintained at a temperature of 36°C for 1 h. The standard ACSF had the following composition (mM): 118.0 NaCl, 2.5 KCl, 2.0 CaCl_2 , 1.0 MgCl_2 , 26.0 NaHCO_3 , 1.25 NaH_2PO_4 , 1.5 myo-inositol, 0.5 sodium ascorbate, 2.0 sodium pyruvate, and 10.0 glucose. After incubation, a single slice was transferred to a recording chamber placed on the stage of an upright microscope, and perfused (3–4 ml/min) with oxygenated ACSF at 32°C. The remaining slices were kept in a holding chamber containing oxygenated ACSF at room temperature until required.

Electrophysiological recording

Whole-cell recordings were made from CA1 pyramidal neurons in hippocampus or the D1-type dopamine receptors expressing medium spiny neurons in the striatum. Patch pipettes (4–6 M Ω) were filled with internal solution containing the following (in mM): 132.0 K gluconate, 6.0 KCl, 6 NaCl, 10.0 HEPES, 2 MgCl_2 , 2.0 NaATP, 0.4 NaGTP, and 0.5 EGTA, pH 7.2–7.4. Signals were amplified by MultiClamp 700B (Molecular Devices), digitized at 10,000 Hz and filtered with a band of 1–2,000 Hz by pCLAMP 10 (Molecular Devices). Off-line analysis was conducted using MATLAB (MathWorks).

Preparation of liposomal nanostructures

Drugs and chemicals that were encapsulated in liposomes were all dissolved in Dulbecco's PBS (catalog #14040133, ThermoFisher Scientific) as follows: Glu, 100 mM L-glutamic acid (Tocris Bioscience); carboxy-fluorescein (CF), 1 mM 6-carboxy-fluorescein (Bachem Feinchemikalien AG); potassium chloride (KCl), 2.6 M KCl plus 1 mM CF; muscimol, 100 mM muscimol (Tocris Bioscience) plus 1 mM CF; D1 Agonist (SKF), 12 mM SKF-38393 hydrochloride (Tocris Bioscience) plus 36 mM L-ascorbic acid sodium salt (Nacalai Tesque); and ascorbic acid, 36 mM L-ascorbic acid sodium salt (Nacalai Tesque).

Liposomal nanostructures were assembled from liposomes, tethering molecules, and hollow gold nanoshells (HGNs). To prepare the liposomes, the following compounds were combined in a flask in the molar ratios of 100:5:5:4:3.5, 1,2-distearoyl-sn-glycero-3-phosphocholine (Echelon Biosciences), cholesterol (Nacalai Tesque), sphingomyelin (Avanti Polar Lipids), 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethylene glycol)-2000] (DSPE-PEG2000, Avanti Polar Lipids), and the tethering molecule DSPE-PEG2000-SH dissolved in chloroform (Nacalai Tesque). A thin film of this lipid mixture was then deposited on the surface of the flask by heating and evaporating the lipid mixture under reduced pressure while warming the flask in warm water. The thin lipid film was suspended in a buffer solution (0.8 ml PBS) containing the drug to be encapsulated by swirling in a water bath at 50°C until all the lipid material was suspended. Immediately afterward, uniformly sized liposomes were obtained by extrusion of the suspension through a 400 nm polycarbonate membrane at a temperature above the transition temperature of the lipids. Based on a study of filter-extruded liposomes by [Hinna et al. \(2016\)](#), we expect that most of the liposomes are unilamellar with a minority of bilamellar (multiwalled) ones in the mix. The suspension of tether-ready liposomes was then placed in a sample vial (15–20 ml capacity).

To link the gold nanoshells, the HGNs were first suspended in HEPES buffer, 10 mM, pH 7.3, gold 8.1 mg/ml. The diameter of the HGNs was \sim 20 nm with absorption in the visible and near-infrared regions. The HGN suspension was added to the liposome suspension in aliquots of 2.9 μl while the solution was agitated on a vortex mixer. After each addition of HGN, the suspension was left unstirred for 5 min. A total of 20 aliquots were added in this manner. Using this method, we estimate that on average one HGN is attached to each liposome. The encapsulation efficiency (\sim 5.3%) was calculated from the percentage volume within the liposomes compared with the total volume of drug solution used for suspending the lipids. To estimate release, we referred to previous work ([Nakano et al., 2014](#)) in which release from liposomes trapped on a carbon fiber was determined by measuring the oxidation current of dopamine. By fitting an exponential curve to a series of release events, the fraction of the cargo released at each event was estimated as 5.8%. The liposome suspension was then placed inside dialysis tubing and dialyzed with PBS buffer, which was stirred during dialysis.

Laser stimulation

We used a two-photon microscope (FV1000, Olympus) to stimulate the liposomal nanostructures. The two-photon microscope has an infrared (890 nm) femtosecond laser, with pulse widths of 100 fs and a repetition rate of 80 MHz. Laser pulses were transmitted through a 60 \times or 40 \times objective lens and focused to a 430 nm spot size in the brain slice, which was then scanned over an area with dimensions of 212 \times 212 μm (60 \times) or 318 \times 318 μm (40 \times). Laser power at the source of 2 W is intensified at the sample (800 kW/cm²) and attenuated by an acousto-optic modulator. A single spot (pixel) had a dwell time of

Whole-cell recordings were made from pyramidal neurons using patch electrode positions in the liposome-injected region. **B**, Enlargement of the area shown by the oblique rectangle in **A**. Laser stimulation was applied to the pyramidal neuron dendritic region by scanning, so that the laser lit small regions one by one, with a laser dwell time of $2 \mu\text{s}$. The small rectangle shows the laser scan crossing the dendrite in the region of liposome injection. **C**, Enlargement of the small rectangle shown in **B**, showing the location of liposomes in relation to dendrites and dendritic spines. Laser-stimulated liposomes release drugs close to dendritic spines. **D**, Liposomes were assembled from components, as described previously. Adapted from the study by Nakano et al. (2014) with permission of the authors. Laser spot, Neuronal structures and liposomes not drawn to scale.

$2 \mu\text{s}$ (160 pulses). The laser stimulation setting was software controlled (FluoView, Olympus).

Plasticity experiments

EPSPs were evoked in D1 receptors expressing medium spiny neurons in the striatum by extracellular stimulation with bipolar electrodes placed in the corpus callosum. Stimulation intensity (0.1–3.0 mA, 0.2 ms duration) was adjusted to evoke baseline EPSPs with amplitudes of 1–6 mV. Baseline EPSPs were recorded for 10 min at a 0.05 Hz stimulation rate.

After the baseline period, a plasticity-inducing stimulation was applied that consisted of 0.2 s suprathreshold postsynaptic current injections paired with 20 Hz electrical stimulation of the cortex to produce a presynaptic and postsynaptic conjunction of activity, which would normally produce long-term depression. Liposomal nanostructures were irradiated with a laser that commenced output from 0.4 s after the onset of the current injection and continued for 0.43 s. This conditioning stimulation protocol was repeated four times at 30 s intervals. The change in EPSP amplitude was evaluated by averaging the responses that were evoked in the period 10–20 min after the conditioning. For group averages, responses

were expressed as the percentage change from the baseline EPSP amplitude. Data are presented as the mean \pm SEM.

Statistical analysis

Statistical analysis was undertaken to test the effectiveness of the liposomes, comparing baseline and evoked responses using Student's *t* test, accepting a significance level of $p < 0.0001$. To determine the significance of the regression analysis, we tested the null hypothesis that the coefficient is equal to zero (no effect), using a significance level set to $p < 0.001$. For the plasticity experiments involving comparison across groups, analysis of variance (repeated measures design) using the general linear model procedures (SPSS, IBM) was used with α set to $p < 0.05$.

Results

In order to test their effectiveness in live brain tissue, liposomal nanostructures were loaded with different agents and injected into area CA1 of the hippocampus. The volume injected was estimated to be 3–5 nl based on the diameter of the volume observed in bright-field images displayed on a monitor screen. Based on the lipo-

somal formulation, we estimated 3.2 million liposomes per nanoliter. To measure release, we made whole-cell recordings from hippocampal CA1 pyramidal cells during exposure of the injected area to laser stimulation (Fig. 1A). The recorded cells were $\sim 500 \mu\text{m}$ distant from the center of the bolus injection, within the pore space of the injected material. As the laser scanned the area, the focal point of illumination passed over the injected liposomal nanostructures in the stratum radiatum (Fig. 1B). Laser-stimulated release of substances caused membrane potential responses, which differed according to the types of receptors or ion channels involved, and their relative location on dendritic spines and dendrites (Fig. 1C).

When liposomes were loaded with the excitatory neurotransmitter glutamate, laser stimulation evoked a transient depolarization of the cell membrane, with a sub-second timecourse (Fig. 2A1). Depolarizations (mean, $4.98 \pm 0.41 \text{ mV}$; $p < 0.0001$ vs baseline; $n = 6$) could be evoked reliably and repeatably (>50 repetitions). Depolarizations occurred with constant latency from the onset of each scan period, consistent with release from one or more liposomes excited at a certain point in the scan. The same intensity of stimulation was able to evoke action potential firing of CA1 pyramidal cells when the injection volume was increased several fold (Fig. 2A2), presumably due to the release of greater quantities of glutamate.

To test the ability of the system to release a wider range of substances than previously possible, we tested liposomes loaded with the GABA_A receptor agonist muscimol, a synthetic compound not available for pulsatile application by electrical, optogenetic, or uncaging methods. Stimulation of muscimol-containing liposomes caused a transient hyper-

polarization (mean, $-1.87 \pm 0.20 \text{ mV}$; $p < 0.0001$ vs baseline; $n = 5$) of the membrane potential (Fig. 2B) consistent with its known pharmacological actions mediated by binding to GABA_A receptors. This demonstrates the possibility of phasic release of a synthetic agent on a subsecond time-scale.

To test their effectiveness in delivery of small ions, liposomes were loaded with potassium chloride. Lipid bilayer membranes are relatively impermeable to potassium chloride, which dissociates into K^+ and Cl^- in water, both of which are charged and have relatively large hydration spheres. Published permeability coefficients for the passage of K^+ and Cl^- through synthetic lipid bilayers are $<10^{-10} \text{ cm/s}$ (Alberts et al., 2002, their Fig. 11-2). Therefore, we tested whether laser stimulation of potassium chloride-containing liposome would cause release, detectable as changes in the membrane potential of the recorded cells. We found that laser stimulation caused neural depolarization (mean, 5.96 ± 0.28 ; $p < 0.0001$ vs baseline; $n = 5$) consistent with a change in the local extracellular concentration of potassium and a consequent shift in the equilibrium potential of the leak conductances of the cells (Fig. 2C). These responses were also repeatable >50 times. Together with the foregoing results, these findings suggest that the method has the potential to provide novel types of control over neural activity by pulsatile application of a broader range of neurochemicals, drugs, and ionic compounds than has previously been possible.

We then investigated the reliability of control of neural function by liposomal release using glutamate-containing liposomes (Fig. 3). We first measured the neural re-

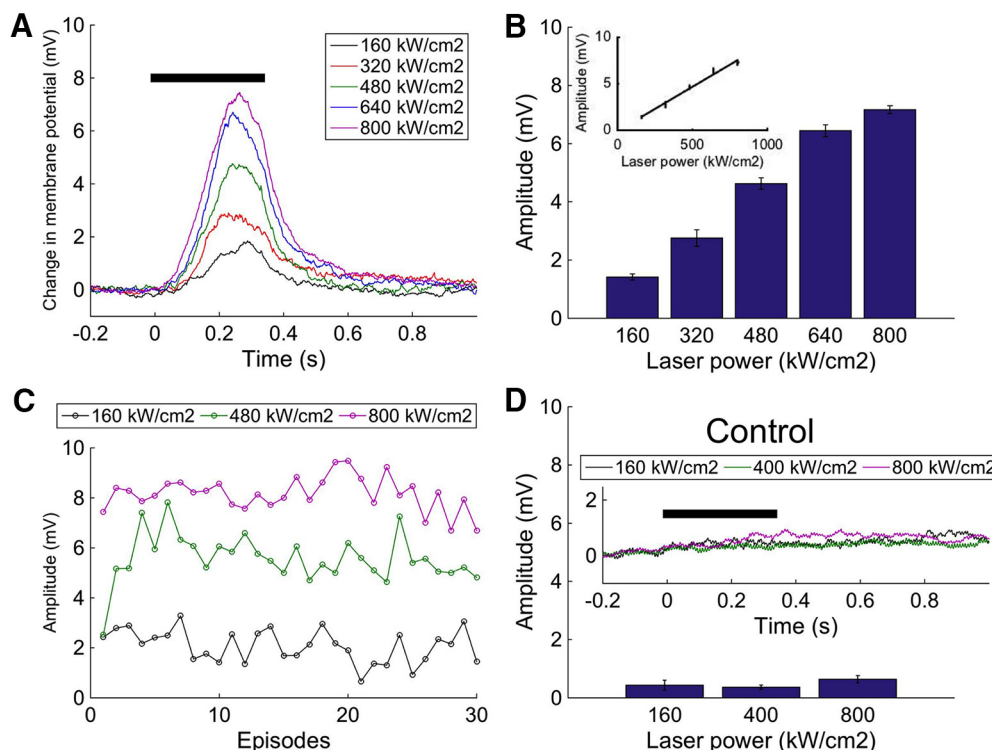

Figure 3. Repeated and amplitude-controlled release by liposome. **A**, Subthreshold neural responses to different laser power. The black bar indicates the laser exposure. Each trace is the average of 30 responses. **B**, Response amplitude for successively increased laser power, showing the average and SEM at each power level. There is a good fit to a regression line $y = 0.0095x - 0.075$ with $R^2 = 0.98$. **C**, Repeatability of subthreshold responses over 30 repetitions of the same stimulus at three different laser power settings. **D**, Control experiment using PBS containing liposome shows small amplitude responses to laser exposure.

sponses to the laser stimulation of glutamate-loaded liposomes as we varied the laser power, using a liposome concentration that produced subthreshold membrane potentials. We found that the amplitude of the responses changed systematically as we varied the laser power, with stronger laser stimulation causing a larger response amplitude (Fig. 3A), and, on average, were approximately linearly related ($r^2 = 0.98$, $p < 0.001$, $n = 30$) to the intensity up to 640 kW/cm² (Fig. 3B). The subthreshold responses were repeatable over many trials (≥ 30) with stable amplitude (Fig. 3C), confirmed statistically by the lack of significant difference of the regression coefficient from zero at 160 kW/cm² ($p = 0.07$, nonsignificant), 480 kW/cm² ($p = 0.47$, nonsignificant), or 800 kW/cm² ($p = 0.41$, nonsignificant).

At higher power settings, even though the exposure period is brief, it is possible that the intensity of stimulation may have direct effects on the membrane potential. In order to confirm that the responses were caused by the glutamate release from laser-stimulated liposome, and not by the direct effects of the laser on the neural processes or liposomes themselves, we exposed PBS-containing liposome to the laser as a control experiment. The laser stimulation to the PBS-containing liposome did not cause depolarizing responses (Fig. 3D), and there was no significant indication of an association of membrane potential with power level ($p = 0.08$, nonsignificant). Together with the significant effects of glutamate-loaded liposomes, these results show that liposomal drug appli-

cation can be used repeatedly to cause membrane potential depolarizations of controlled amplitude, thus providing a novel means of interfacing light and neural activity that does not require genetic manipulation or depend on the chemical properties of the agents.

To investigate whether the liposomal nanostructures could be used to produce physiological changes by the release of specific dopamine agonist drugs, we tested the effectiveness of liposomal nanostructures in modulating activity-dependent synaptic plasticity in the striatum. Previously, the neuromodulator, dopamine—acting via dopamine D1 receptors—has been known to modulate synaptic plasticity in the striatum (Reynolds et al., 2001). However, tonic stimulation of dopamine D1 receptors by dopamine D1-selective agonist drugs does not have this effect. We hypothesize that the effect requires phasic activation of the receptor, because of the rapid desensitization of dopamine D1 receptors when constantly exposed to agonists (Ofori et al., 1993) and previous studies showing that pulsatile application, but not bath application, of dopamine causes long-term potentiation (Wickens et al., 1996).

To test this hypothesis, we used liposomes loaded with the dopamine D1 agonist SKF-38393, and laser stimulation to phasically activate the dopamine D1 receptors. Using corticostriatal slices from transgenic mice in which EGFP is selectively expressed in D1 receptor-expressing medium spiny neurons of the striatum, we measured EPSPs before and after an experimental treatment involv-

Figure 4. Dopamine D1 receptor-mediated synaptic plasticity. **A**, The top trace shows membrane potential during conditioning. Lower traces show the conditioning stimulation protocol. Conditioning stimulation was a combination of cortical stimulation (four pulses at 20 Hz) and suprathreshold postsynaptic current injection paired with cortical stimulation. Laser stimulation (0.43 s scan, 2 μ s dwell time at 400 kW/cm²) was delayed 0.4 s. **B**, An example of the change in the synaptic responses. The synaptic response increased after the conditioning using SKF-38393 containing liposome, while resting membrane potentials and input resistance remain unchanged. **C**, Examples of EPSPs before and after conditioning. The black line indicates preconditioning, and the red line indicates postconditioning corresponding to the bar in **B**. **D**, Group average of the change in the synaptic efficacy using SKF containing liposome (red) or ascorbic acid containing liposome (black). Values are reported as the mean \pm SEM.

ing activity and phasic dopamine D1 receptor stimulation. EPSPs were evoked in the medium spiny neurons by stimulating the corpus callosum, and test responses were recorded before and after an experimental treatment.

Liposomes loaded with SKF-38393 plus ascorbic acid in PBS (D1 agonist experimental group), or ascorbic acid alone in PBS (vehicle controls) were injected into the slice in advance of the recording. Ascorbic acid was used to reduce oxidation of the dopamine agonist. To induce synaptic plasticity, electrical stimulation of presynaptic inputs was repeatedly paired with firing of the postsynaptic neurons, a protocol that is expected to produce long-term depression based on previous studies (Wickens et al., 1996; Shindou et al., 2011). Phasic release of SKF-38393 plus ascorbic acid or ascorbic acid alone (Fig. 4A) was paired with the electrical stimulation. After pairing, the amplitude of EPSPs in the DA agonist group increased significantly relative to that of the controls, and remained increased for the duration of the recording (mean normalized EPSP 1–20 min after pairing: control, 0.81 ± 0.10 mV, $n = 7$; SKF-38393, 1.12 ± 0.08 mV, $N =$

11; $p < 0.05$, Fig. 4B,C), long outlasting the application of SKF-38393, indicating a modulatory effect on long-term plasticity of synaptic responses. The example cell shown exhibited a very large potentiation, possibly indicating a favorable location of liposomes relative to the synapses mediating the postsynaptic response, while other cells showed fewer dramatic changes, as indicated in the group averages (Fig. 4D, SKF-38393). The cell shown exhibited the largest potentiation seen, well above the average, was treated as an outlier, and was not included in the statistical analysis. In contrast, the amplitude of EPSPs decreased after conditioning using liposome loaded with only ascorbic acid (Fig. 4D, controls). These findings support the hypothesis that phasic activation of dopamine D1 receptors is sufficient for the induction of dopamine D1 receptor-dependent synaptic plasticity.

A crucial question is the suitability of the liposomes for use under *in vivo* conditions. To test the durability of liposome in live animals, we made injections of glutamate- and 6-CF-containing liposomes into the cerebral cortex stereotaxic coordinates [anteroposterior (AP), 1.1; medio-

Figure 5. Liposome functionality after 1 week *in vivo*. **A**, Liposomes were stereotaxically injected into cerebral cortex at the location shown. lateral (ML), 1.5; dorsoventral (DV), 1.4; Fig. 5A], and tested functionality at 1 week and 1 month after the injection. One week after injection, following the preparation and superfusion of brain slices during maintenance and in the recording chamber, opacities indicating the presence of liposomes could be seen under infrared differential interference contrast illumination at low magnification (Fig. 5B). Whole-cell recordings from pyramidal neurons in these slices showed that laser stimulation at low power (8 kW/cm^2) evoked subthreshold membrane potential depolarizations (mean, 7.12 ± 0.30 mV; $p < 0.0001$; $n = 10$; Fig. 5C). Suprathreshold responses were evoked at higher laser power (160 kW/cm^2 ; Fig. 5D). As previously shown for acutely injected liposomes, the transient depolarizations could be evoked reliably and repeatedly over several trials (Fig. 5E). These findings show that liposomes survive in the brain of living animals and remain functional for at least 1 week.

One month after injection into a similar cortical region (AP, 0.6; ML, 1.5; DV, 1.5), opacities could still be seen (Fig. 6A). In slices made from these animals, laser stimu-

lation at low power evoked minimal release of CF (Fig. 6B). Substantial release was observed at higher laser stimulation power (Fig. 6C), and this was associated with subthreshold depolarization (Fig. 6D). However, with repeated stimulation the response amplitude decreased over 25 release episodes, suggesting that after 1 month *in vivo* the proportion of fragile liposomes has increased (Fig. 6E).

Discussion

We have demonstrated that drug-encapsulated liposomes provide an interface with neural activity when stimulated by femtosecond laser pulses. This technique allows the encapsulation of a wide variety of neurochemically active substances, including glutamate, potassium chloride, and muscimol and specific dopamine agonists. By varying laser power, it is possible to control the release of neurochemicals, in turn modulating the neural responses. The evoked neural responses were repeatable and stable. Importantly, the liposomes are compatible

with brain tissue and remain stable in the living brain for long periods.

The mechanism of light-induced release from gold-tethered liposome structures is not yet known, but there are several possibilities and clues from previous studies. We previously proposed that the following two different processes are involved: a process that may involve one-time destruction of a fragile subset of the liposomes; and a more common nondestructive and repeatable process in which the liposome wall becomes temporarily permeable to the contents and then reseals, allowing multiple release events. Paasonen et al. (2007) proposed that HGNs, via the linker molecules, may transfer heat to the liposomal wall and increase its fluidity. Similarly, Wu et al. (2008) suggest that release is caused by transient cavitation due to microbubble formation and collapse within the liposome wall. Both mechanisms involve steep tempera-

ture gradients that require femtosecond pulse irradiation. Importantly, the present formulation is dominated by the nondestructive process, as evidenced by SEM confirmation of the persistence of liposomal nanostructures before and after light-stimulated release (Nakano et al., 2014).

A particular advantage of this technique, compared with other optical stimulation techniques, is the ability to encapsulate a variety of chemicals. This allows the controlled release of not just intrinsic neurotransmitters, but also artificial molecules, such as selective receptor agonists, antagonists, and ion channel blockers. This enables the stimulation of particular subtypes of receptors or the blockade of specific ion channels, making a large arsenal of experimental tools available for reliable and repeatable delivery on a sub-second timescale. In comparison, optogenetic neural manipulation is limited to releasing naturally synthesized neurotransmitters from genetically modified neurons. While

optogenetics provides unparalleled advantages for manipulating existing neural systems, it cannot substitute for neural functions that have been lost due to neurodegeneration or release novel, artificially synthesized pharmacological agents. Similarly, uncaging techniques are limited to compounds that have a molecular structure that is suitable for covalent binding to caging moieties, in turn limiting the possibilities of neural interfacing.

By varying laser intensity and pulse-timing parameters, laser-stimulated release from liposomes can be flexibly controlled. This flexibility is an advantage over caged compounds, which have a threshold-like, nonlinear characteristic due to the photolytic processes involved in uncaging, and do not produce smoothly graded variation in release amount. The graded release that is possible from liposomes thus provides a wider and more continuous range over which neuronal function can be manipulated.

The combination of spatiotemporally controlled release, along with the variety of available neurochemicals, also allows for other novel studies of neural functioning, which are not possible with existing methods. Further developments in the architecture of the gold nanoparticles tethered to the liposomes may enable selectivity in excitation wavelengths, such that, in principle, one could inject two populations of liposomes, both loaded with different neurochemicals, that respond to different wavelengths of light. This allows the possibility of multichannel stimulation. Last, we note that liposomes are highly biocompatible, and are not toxic to living tissue. We have demonstrated that the liposomes survived and stayed at the injected site for weeks while retaining the ability to release the encapsulated neurochemicals. These characteristics are well suited for *in vivo* experiments and provide the possibility of addressing neurological diseases in the future.
