ABSTRACT

Stability is a fundamental requirement for both biological and engineered neural circuits, yet it is surprisingly difficult to guarantee in the presence of recurrent interactions. Standard linear dynamical models of recurrent networks are unreasonably sensitive to the precise values of the synaptic weights, since stability requires all eigenvalues of the recurrent matrix to lie within the unit circle. Here we demonstrate, both theoretically and numerically, that an arbitrary recurrent neural network can remain stable even when its spectral radius exceeds 1, provided it incorporates divisive normalization, a dynamical neural operation that suppresses the responses of individual neurons. Sufficiently strong recurrent weights lead to instability, but the approach to the unstable phase is preceded by a regime of critical slowing down, a well-known early warning signal for loss of stability. Remarkably, the onset of critical slowing down coincides with the breakdown of normalization, which we predict analytically as a function of the synaptic strength and the magnitude of the external input. Our findings suggest that the widespread implementation of normalization across neural systems may derive not only from its computational role, but also to enhance dynamical stability.

I. INTRODUCTION

Divisive normalization is a form of multiplicative neuronal modulation occurring in the brain whereby the response of an individual neuron is divided by the summed activity of other similarly tuned neurons. Introduced in the 1990s to explain nonlinearities in the responses of neurons in the primary visual cortex [1, 2], it was later invoked to interpret a larger body of physiological data in the olfactory [3] and auditory [4] cortical areas, as well as in cognitive processes such as attention, working memory and value-based decision making [5–8]. Simply put, normalization explains how the response of a given neuron, which is selective for a specific stimulus, is suppressed by different stimuli that would elicit a weaker or no response if they were presented alone, as illustrated in Fig. 1a. Notwithstanding the general character of this neural computation, different biophysical mechanisms may perform normalization in different neural systems, including intracortical shunting inhibition [2, 9], thalamocortical synaptic depression [10], pre-synaptic inhibition [3], recurrent amplification (i.e., amplifying weak inputs more than strong inputs) [11–15], to name the most prominent ones. In our computational model, we implement divisive normalization via a multiplicative interaction between the principal neurons and a population of (secondary) inhibitory neurons, as illustrated in Fig. 1b,c. This model, which goes by the name of ORGaNICs [16], is much like the linear recurrent circuits introduced in the 1980s [17], but with a multiplicative gain on the recurrent term that implements normalization (see Fig. 1b,c).

ORGaNICs have been proved to be unconditionally stable when the recurrent weight matrix is the identity [18]. Here we elaborate on the relationship between normalization and stability in the case of a generic recurrent weight matrix, such as a large random matrix drawn from the Gaussian Orthogonal Ensemble (GOE) [19]. We find that ORGaNICs models with recurrent weights drawn from the GOE ensemble are stable even when the spectral radius of the recurrent matrix is larger than 1, thanks to the normalization mechanism. Quantitatively, ORGaNICs push the stability limit of linear models by more than 100% (see phase diagram of stability in Fig. 5). Perhaps more importantly, we find that the transition to an unstable fixed point is preceded by critical slowing down [20, 21] in the neural dynamics (where the circuit is slow to reach the fixed point or to recover from small perturbations), the onset of which co-occurs with the breakdown of normalization in the neural responses. Remarkably, this result implies that the breakdown of normalization is an early warning signal for the loss of stability of the neural network, a signal we can predict analytically in terms of the recurrent interaction strength (i.e., the variance of the recurrent weights) and the magnitude of the external input.

II. ORGaNICs MODEL OF NORMALIZATION

In its simplest form, normalization works by dividing a neuron's total input by the sum of all inputs to N neurons in the normalization pool [1], expressed mathematically by the formula

$$y_i^+ = \frac{z_i^2}{\sigma^2 + \sum_{j=1}^{N} z_j^2} \ , \tag{1}$$

where y_i^+ is the firing rate of neuron i; $z_i \in [0, 1]$ is its input drive, defined as a weighted sum of the responses of a population of presynaptic neurons; and σ is the semisaturation constant, whose experimental value in primary visual cortex (V1) is $\sigma \sim 0.1$ [22]. The purpose of the normalization mechanism is to normalize the output responses y_i^+ via the ratio between the input drive of an individual neuron and the input drives summed across all of the neurons [5, 16, 23–29]. Two important predictions of the normalization equation (1) as applied to visual cortex are illustrated in Fig. 1a, namely response saturation and cross-orientation suppression.

Since Eq. (1) describes a neural process that is static, it is natural to ask how the output responses $y_i^+(t)$ evolve in time towards the normalized state given by Eq. (1). That is: how does a neural circuit accomplish normalization? A mathematical way to achieve normalization dynamically is to couple the output responses of the principal neurons, $y_i^+(t)$, to a secondary neuronal population, represented by a single variable $a(t)$, that acts as a multiplicative inhibitory modulator. The class of dynamical systems implementing divisive normalization in this way is known as ORGaNICs [16, 18]. The simplest ORGaNICs involve only two neurons and is described by the following dynamical equations

$$\begin{cases} \tau_y \dot{y} = -y + z + (1 - a^+)y \\ \tau_a \dot{a} = -a + \sigma^2 + y^+ a \ , \end{cases} \tag{2}$$

where $y(t)$ and $a(t)$ represent the membrane potentials (relative to an arbitrary threshold potential that we take to be 0) of the excitatory (E) and inhibitory (I) neurons, respectively, and y^+ and a^+ are the corresponding firing rates. The 2-neuron circuit described by Eq. (2) is depicted in Fig. 1b. The firing rate of the E neuron y^+ is related to the membrane potential by squaring, $y^+ = ky^2$ [1, 30–33] (henceforth we set the dimensional proportionality factor $k = 1$), while the firing rate of the I neuron is given by $a^+ = \sqrt{\lfloor a \rfloor}$, where $\lfloor x \rfloor = \max(0, x)$ (see Supplementary Section V E and Fig. S10 for alternative activation functions); and $\tau_y > 0$, $\tau_a > 0$ are the neurons' intrinsic time constants. The circuit in Eq. (2) models, for example, the response of a neuron in the primary visual cortex with z proportional to stimulus contrast, as seen in Fig. 1b. At the

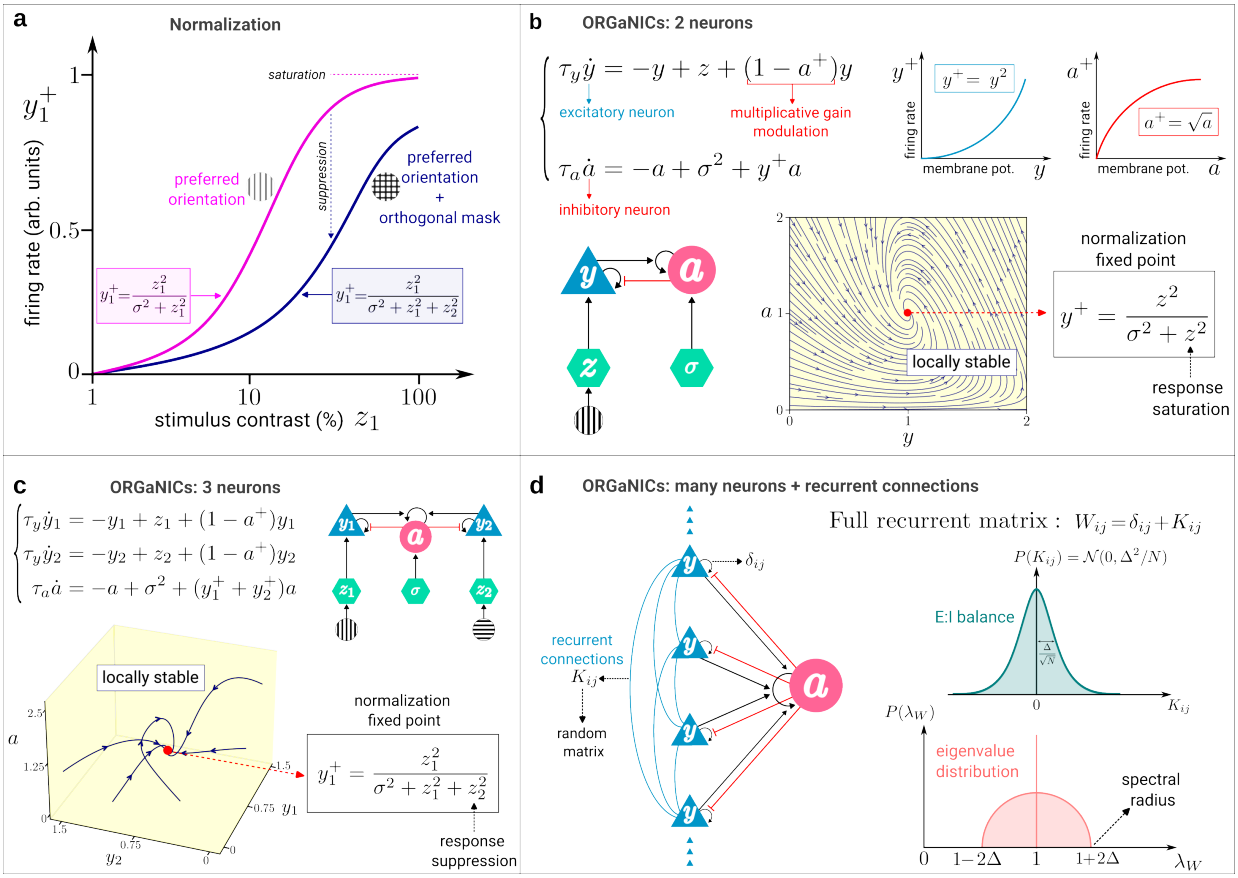

FIG. 1. **Normalization via ORGaNICs. a,** An orientation selective principal neuron y_1 in primary visual cortex (V1) fires when the stimulus orientation matches its preferred orientation (pink curve). The larger the stimulus contrast z_1, the greater the strength of the response. The firing rate y_1^+ can be modeled by a nonlinear response function that saturates at high contrast. When a second grating stimulus z_2 with orientation perpendicular to the preferred one (*viz.* an orthogonal mask) is presented simultaneously with stimulus z_1, there is a rightward shift of the response function y_1^+ (blue curve). The suppressive effect of the orthogonal mask can be modeled by an extra term z_2^2 in the denominator of the response function. **b,** The saturation of the firing rate y^+ at high contrast z can be obtained as the fixed point of the 2-neuron circuit in Eq. (2) involving the principal neuron y and a secondary inhibitory neuron a that acts on y as a multiplicative gain modulator. This fixed point is locally stable for any value of the time constants τ_y, τ_a and the semisaturation constant σ. **c,** The suppressive effect of the orthogonal mask can be modeled by the fixed point of the 3-neuron circuit, where y_1 and y_2 respond selectively to the vertical and horizontal orientations, respectively, and a performs the multiplicative gain modulation on both y_1 and y_2. This fixed point is locally stable for any value of the parameters. Notice that neurons y_1 and y_2 do not interact directly, but only through neuron a, i.e., there are no recurrent connections between the principal neurons. **d,** Recurrent connections are included via the weight matrix W composed of the identity I plus a random matrix K modeling lateral synaptic connections between the principal neurons. The weights K_{ij} are E:I balanced (i.e., mean 0) and sampled from a symmetric Gaussian distribution such that the spectral radius of W is equal to $1+2\Delta$ in the limit where the number of neurons N goes to infinity.

fixed point, the principal neuron y follows the normalization equation (1), i.e. $y^+ = \frac{z^2}{\sigma^2+z^2}$, which explains the *saturation* of the firing rate at large contrast z. Moreover, this normalization fixed point is always locally stable [18] (see Fig. 1b, c).

Although it has been proved that a two-neuron ORGaNICs is unconditionally stable for any strength of the recurrent drive [18], the stability of a high-dimensional circuit with arbitrary recurrent connections has not been studied. Thus we ask: what happens when arbitrary recurrent connections (i.e. interactions) are included in the circuit? Do ORGaNICs still accomplish normalization? Is stability preserved?

To answer these questions we include recurrent connections between the principal neurons as described by the following set of differential equations

$$\begin{cases} \tau_y \dot{y_i} = -y_i + z_i + (1 - a^+) \sum_{j=1}^{N} W_{ij} y_i \\ \\ \tau_a \dot{a} = -a + \sigma^2 + \left(\sum_{i=1}^{N} y_i^+ \right) a \ , \end{cases} \tag{3}$$

where the recurrent weight matrix W captures lateral connections between the principal neurons, as shown in Fig. 1d. Our goal is twofold: first, we determine the conditions on W and z such that normalization still approximately holds for the circuit in Eq. (3); second, we investigate the consequences of the breakdown of normalization, due to strong recurrent interactions, for the stability of the whole neural network.

III. LOSS OF NORMALIZATION AS AN EARLY WARNING SIGNAL OF NEURODYNAMICAL INSTABILITY

A. Numerical solution of the fixed point

We start with a numerical study of the stability of the fixed-point of Eq. (3) and then we derive our analytical solution perturbatively, supported by the exact numerical result. We express the recurrent matrix as the sum of the identity plus a perturbation as

$$W = I + K \ , \tag{4}$$

where K is a symmetric GOE random matrix [19] whose entries K_{ij} are independent and identically distributed Gaussian random variables with zero mean and variance Δ^2/N if $i = j$ or $\Delta^2/2N$ if $i \neq j$, corresponding to balanced excitation and inhibition. The scaling of the variance with $1/N$ ensures that the spectral radius $\rho(K)$ does not grow with the number of neurons N, but is

controlled only by Δ (specifically, $\rho(K) = 2\Delta$, hence $\rho(W) = 1 + 2\Delta$, see Fig. 1d). The choice of a random matrix to study the stability of large systems of differential equations can be traced back to the seminal work of May on the stability of complex ecosystems [34], that initiated a new field in theoretical ecology [35, 36] as well as the famous diversity-stability debate [37–39]. Methods based on random matrix theory are also well suited to model very large neural circuits whose experimental parametrization would be otherwise unfeasible [40]. Here, we follow a similar approach with the goal of deriving a condition on the recurrent interaction strength Δ such that the output responses y_i still approximately satisfy the normalization equation (1), and then study the consequences of the breakdown of normalization on the system's stability. We note, *en passant*, that a linear model (i.e. a model where $a \equiv 0$) would become unstable as soon as the spectral radius of W gets larger than 1, i.e. a soon as $\Delta > 0$ (see Fig. 5). In contrast, the nonlinear model described by Eq. (3) can be stable even when W has spectral radius larger than 1, as we show next.

In Figure 2a,b we show the numerical solution of the fixed point of Eq. (3) (see Supplementary Section V A for details on the numerical methods). We plot the mean and variance of the fixed point membrane potentials, y_i, over the ensemble of random recurrent matrices K, as a function of the input drive z for $\Delta = 0.05$ and $\Delta = 0.25$. We find that the output responses, on average, still follow the normalization curve, i.e. $\mathbb{E}[y_i] \sim z_i/\sqrt{\sigma^2 + ||\mathbf{z}||^2}$ (noting that membrane potential in this model is the square root of firing rate), but pick up a variance that increases with increasing Δ. For sufficiently large Δ we observe that the circuit's convergence to its fixed point, as measured by the real part of the largest eigenvalue λ of the Jacobian evaluated at the fixed point [41], becomes very slow (i.e. $\lambda \sim 0$ corresponding to a convergence time $t_{conv} = \frac{1}{|\lambda|} \gg 1$), as seen in Fig. 2b. This phenomenon, called **critical slowing down**, is widely considered to be an important early warning signal that anticipates the system's tipping point [20, 21, 42].

To identify the onset of critical slowing down we plot in Fig. 3a the probability distribution $P(\lambda)$ of the real part of the largest eigenvalue of the Jacobian at the fixed point for circuits with $N = 1000$ neurons, weak input drive $z = 0.01$, and different values of the recurrent interaction strength Δ. At small Δ, $P(\lambda)$ has a gap from 0, which closes when Δ approaches the critical value $\Delta = \Delta_{csd}$, signaling the onset of critical slowing down. To get a more precise estimate of Δ_{csd}, we extrapolate the mean and variance of $P(\lambda)$ in the limit $N \to \infty$ via finite size analysis, yielding the asymptotic mean and variance shown in Fig. 3b (see Supplemenatry Section V B and Figs. S2, S3 for details on the extrapolation to $N \to \infty$). The variance goes to zero in the large N limit, meaning that $P(\lambda)$ becomes a δ-function sharply peaked around its mean. The mean vanishes at

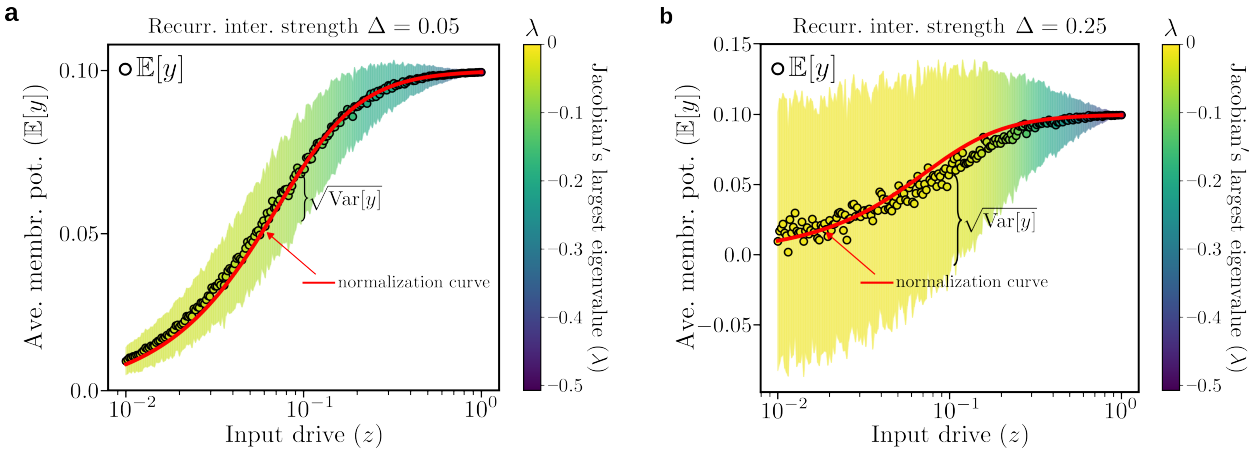

FIG. 2. **Numerical solution to the ORGaNICs' fixed point equations. a,** Fixed-point average membrane potential $\mathbb{E}[y]$ (open circles) as a function of the input drive z (here we use $N = 100$ neurons and $z_i = z/\sqrt{N}$, called *delocalized* input drive) for an E:I balanced recurrent network K with zero mean and std. dev. $\Delta = 0.05$, obtained by solving numerically Eq. (3) using the explicit Euler method with time step $dt = 0.05 \times \tau_y$. The semisaturation constant is $\sigma = 0.1$ and the neurons' time constants τ_y and τ_a are equal. Each point is an average over 1000 realizations of the synaptic weight matrix K. The neural response still follows, on average, the normalization Eq. (1) (solid red curve), but picks up a variance across different random samples of recurrent synaptic weights, represented by the shaded area around the data points. The color code of the shaded area represents the real part of the largest eigenvalue of the Jacobian at the fixed point averaged over samples, whose value is well below 0 for all z. **b,** For $\Delta = 0.25$ the average response is still normalized, but the variance (across random samples of the recurrent weights) is bigger than in (**a**) (see Fig. S1 for more Δ values). For sufficiently small input drives, the largest eigenvalue of the Jacobian at the fixed point becomes very small ($\lambda \sim 0$). As a consequence, convergence to the fixed point occurs on time scales much longer than the time constant τ_y of individual neurons, a phenomenon known as critical slowing down (see also Fig. 3c).

$\Delta = \Delta_{csd}$ and remains zero in the whole interval $\Delta_{csd} \leq \Delta \leq \Delta_c$ (Fig. 3b). In this interval the neural dynamics are very slow (compared to the neuron's intrinsic time scale τ_y) to reach the fixed point, as illustrated by some representative trajectories shown in Fig. 3c. Eventually, for $\Delta \geq \Delta_c$, the circuits enter first into limit cycles and then become unstable (see Fig. 5).

Next we demonstrate that the onset of critical slowing down occurs precisely when normalization of the neural responses breaks down.

B. Loss of normalization predicts critical slowing down

To quantify the loss of normalization, we look at the mean and variance (across many instances of the recurrent matrix K) of the neural responses. As seen in Figure 2, the neural response y_i

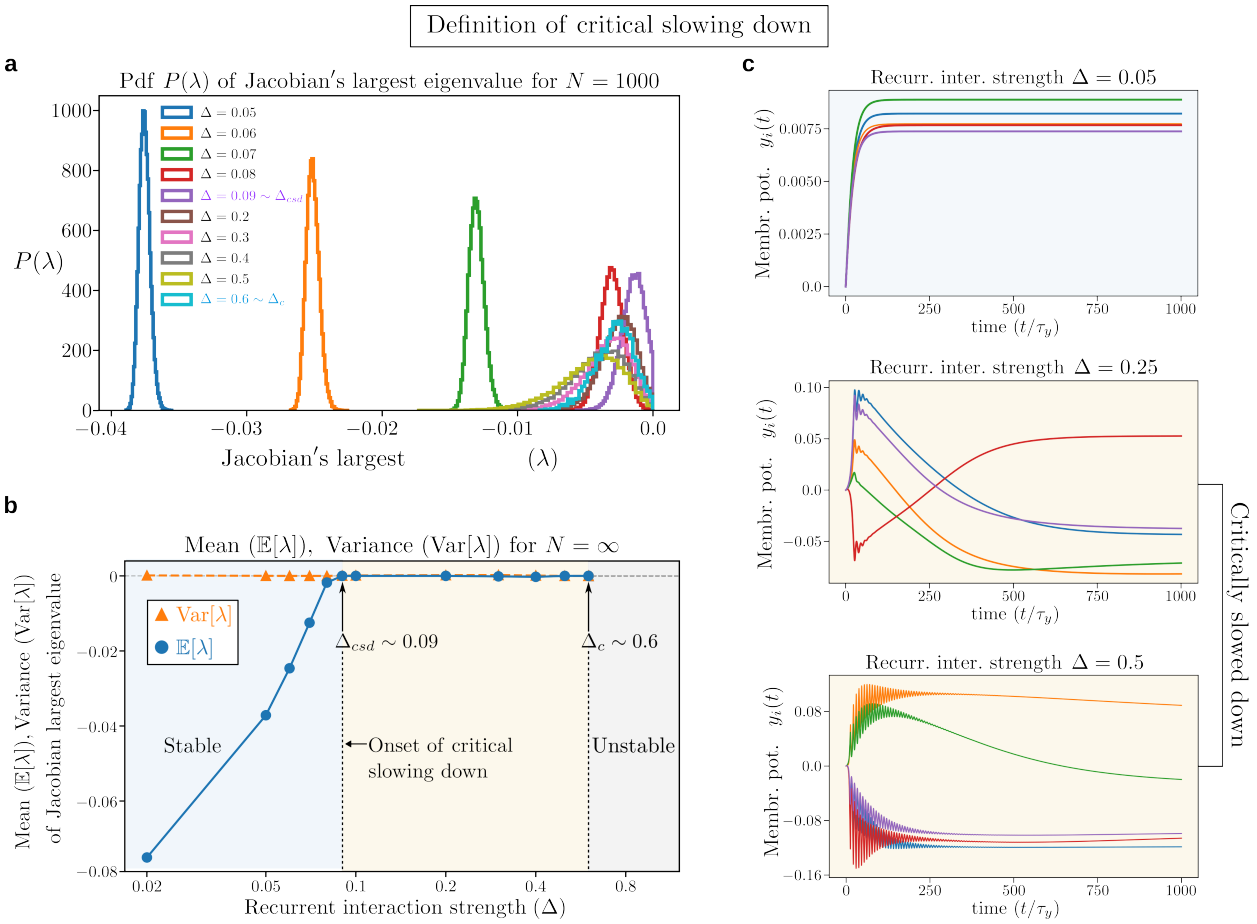

FIG. 3. **Definition of critical slowing down. a,** Probability distribution of the largest eigenvalue of the Jacobian at the fixed point for a network with $N = 1000$ neurons (see Fig. S2 for different sizes); input drive $z_i = 0.01/\sqrt{N}$ (very weak input drive); semisaturation constant $\sigma = 0.1$; and several values of the recurrent interaction strength Δ. For small Δ the distribution $P(\lambda)$ is gapped from 0 and, as a consequence, the neural responses converge quickly to their fixed points. When Δ increases, the gap shrinks and then closes at $\Delta = \Delta_{csd}$, signaling the onset of critical slowing down. For $\Delta_{csd} \leq \Delta \leq \Delta_c$ the neural responses converge slowly to their fixed points. For $\Delta \geq \Delta_c$ the neural circuits do not have stable fixed points, but exhibit limit cycles and, for even larger Δ, they eventually become unstable (see Fig. 5). **b,** Mean, $\mathbb{E}[\lambda]$, and variance, Var(λ), of the largest eigenvalue of the Jacobian extrapolated to $N \to \infty$ as a function of Δ (see Fig. S3 for details on the extrapolation). The model parameters' values are as in (**a**). Since the variance is zero in the $N \to \infty$ limit, $P(\lambda)$ tends to a delta function $\delta(\lambda - \mathbb{E}[\lambda])$, thus making the determination of Δ_{csd} well defined as the value at which the mean $\mathbb{E}[\lambda]$ goes to zero. Slowing down persists up to the critical value Δ_c, beyond which there are no stable fixed points (see Fig. 5). **c,** Representative trajectories of the neural responses $y_i(t)$ in the stable phase ($\Delta = 0.05$) and in the critically slowed down phase ($\Delta = 0.25, 0.5$), showing the slowness of the dynamics in reaching the fixed point. (see Fig. S4 for trajectories of all the neurons and Figs. S9, S12 for the analysis of the frequency of oscillations).

can be described by its expected value plus the standard deviation: the expected value follows the

normalization equation and the standard deviation quantifies the departure from normalization. Therefore, neuron i loses normalization as soon as the standard deviation of its response is equal to its mean value, as given by the formula

$$\sqrt{\text{Var}[y_i]} = \mathbb{E}[y_i] \quad \text{(loss of normalization)} \ , \tag{5}$$

and illustrated in Fig. 4a,b. Equation (5) defines implicitly a threshold $\Delta_{loss}(z)$ marking the

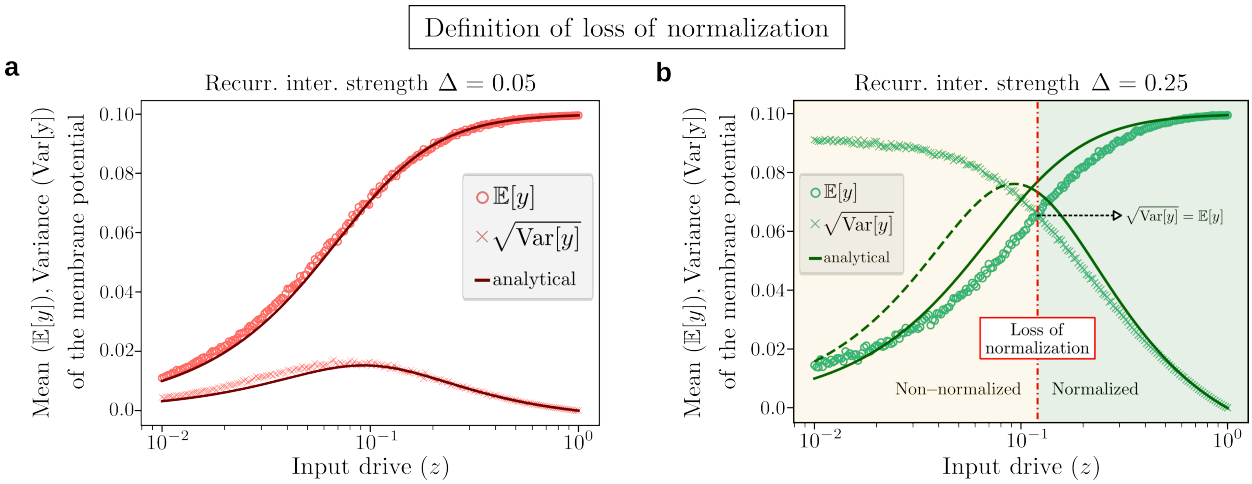

FIG. 4. **Definition of loss of normalization. a,** Mean, $\mathbb{E}[y]$, (circles) and standard deviation, $\sqrt{\text{Var}[y]}$, (crosses) of the fixed point membrane potential as a function of the norm z of the input drive $z_i = z/\sqrt{N}$ for an E:I balanced recurrent network K with zero mean and std. dev. $\Delta = 0.05$. We used $N = 100$ neurons and averaged over 10^4 realizations of K. The standard deviation is smaller than the mean for all values of z, so the neural responses are always normalized. The analytical approximations (solid curves) for the mean and standard deviation Eq. (7) of the response, computed with perturbation theory, show a good agreement with the exact numerical solutions. **b,** Same as in **a**, but using $\Delta = 0.25$. The standard deviation is smaller than the mean ($\sqrt{\text{Var}[y]} < \mathbb{E}[y]$) at large z, but it is larger than the mean ($\sqrt{\text{Var}[y]} > \mathbb{E}[y]$) at small z. The value of z where the two curves cross each other, given by Eq. (5), defines the threshold at which the neural responses lose normalization (dashed red line). The analytical approximations are in good agreement with numerical simulations for almost all values of the input drive (notice the log scale on the abscissa), but become less accurate at small z where the responses are non-normalized and perturbation theory breaks down, another indication of a major shift in the circuit's behavior.

boundary between the phase in which responses are normalized and the phase where they are not. We compare the loss of normalization threshold $\Delta_{loss}(z)$ with the critical slowing down threshold $\Delta_{csd}(z)$ in Fig. 5, showing excellent agreement between the two at all values of the input drive z, thus demonstrating that the onset of critical slowing down co-occurs with the loss of normalization of the neural responses, which represents our most important result.

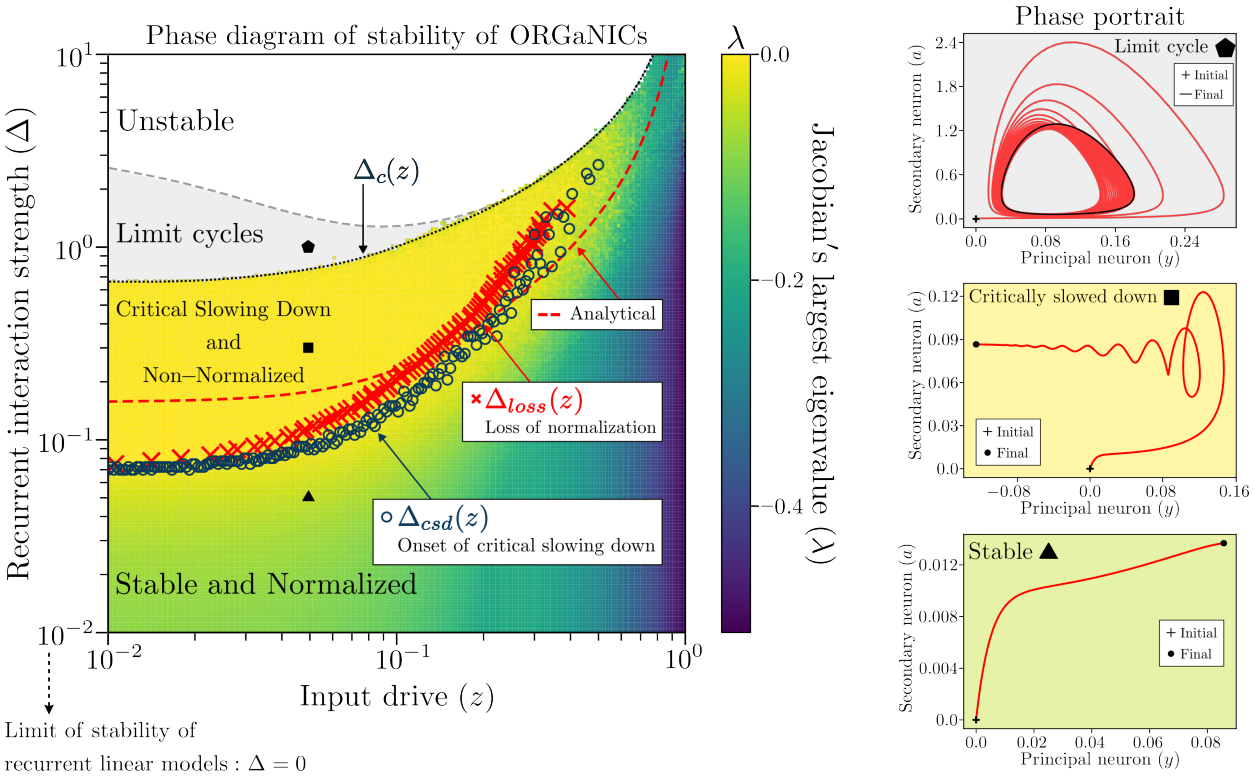

FIG. 5. **Loss of normalization predicts the onset of critical slowing down.** Real part of the largest eigenvalue λ of the Jacobian at the fixed point in the (z, Δ) plane obtained by solving numerically Eq. (3) for E-I balanced networks with $N = 100$ neurons (see Supplementary Section V F and Fig. S11 for the case of E-I imbalanced networks); delocalized input drive $z_i = z/\sqrt{N}$; semisaturation constant $\sigma = 0.1$; neurons' time constants $\tau_y = \tau_a$; using a mesh of 200×200 values of z and Δ. Color represents the maximum value of λ across 100 random samples of the recurrent synaptic weights. Circuits with small Δ are stable at any value of the input drive z and converge quickly to their fixed point, as indicated by a strictly negative eigenvalue $\lambda < 0$ and by the *Stable* phase portrait in the (y, a) plane (where a is the inhibitory neuron). Conversely, for $\Delta_{csd} \leq \Delta < \Delta_c$, the circuits exhibit critical slowing down, in that they approach the fixed point very slowly, as indicated by $\lambda \sim 0$ and by the spiral attractor in the *Critically slowed down* phase portrait. The points marking the onset of critical slowing down (open blue circles) are determined by the closing of the gap in the distribution $P(\lambda)$ (see Fig. 3), which define the curve $\Delta_{csd}(z)$. The points defining $\Delta_{loss}(z)$ (red crosses) represent the boundary between the normalized and non-normalized phases and are determined via Eq. (5) (see Fig. 4). Loss of normalization predicts well the onset of critical slowing down, i.e. $\Delta_{loss}(z) \approx \Delta_{csd}(z)$, thus providing a good early warning indicator of neurodynamical tipping points. For sufficiently large Δ the neural circuits exhibit limit cycles, as shown in the *Limit cycle* phase portrait, and for even larger Δ they become unstable. Notice, however, that simple linear recurrent models would become unstable as soon as $\Delta > 0$, while adding normalization pushes the stability limit much further.

An immediate consequence of this correspondence is that we can predict theoretically the onset of critical slowing down by calculating $\Delta_{loss}(z)$, which is a simpler quantity to estimate analytically,

as explained next. To compute the mean and variance entering in equation (5), we must first find the fixed point of the dynamical system in Eq. (3), which, unfortunately, cannot be expressed in closed form. To overcome this obstacle, we use perturbation theory to approximate the exact solution. We look for a solution to the fixed point equations in the form of a series $y_i = y_i^{(0)} + y_i^{(1)} + ...$, where $y_i^{(0)}$ is given by the normalization equation (1), and $y_i^{(1)}$ is of the same order of magnitude as the perturbation K. Inserting this expansion in Eq. (3) we find the approximate fixed point solution (see details in Supplementary Section V C):

$$y_i \approx \frac{z_i}{\sqrt{\sigma^2 + ||\mathbf{z}||^2}} + \left(\sum_j K_{ij} z_j - z_i \frac{\mathbf{z}^T K \mathbf{z}}{\sigma^2 + ||\mathbf{z}||^2} \right) G(||\mathbf{z}||) \ , \tag{6}$$

where $G(z) = \frac{1-\sqrt{\sigma^2+z^2}}{\sigma^2+z^2}$ and $||\mathbf{z}||^2 = \mathbf{z}^T\mathbf{z}$. The last term on the right hand side of Eq. (6) quantifies the impact of the recurrent interactions on the normalization fixed point. Taking the expectation on both sides, and using the fact that the K_{ij}'s have zero mean, we find $\mathbb{E}[y_i] \approx \frac{z_i}{\sqrt{\sigma^2+||\mathbf{z}||^2}}$, meaning that the neural responses still follow, on average, the normalization equation, as seen in Figure 4a,b. Departure from normalization is quantified by the variance of y_i. The calculation of $\mathrm{Var}[y_i]$ yields the following general expression (see Supplementary Section V C for details)

$$\mathrm{Var}[y_i] \approx \frac{\Delta^2}{2N} \left[||\mathbf{z}||^2 - z_i^2 + \frac{2 z_i^2 \sigma^4}{\left(\sigma^2 + ||\mathbf{z}||^2\right)^2} \right] G^2(||\mathbf{z}||) \ , \tag{7}$$

which depends on the magnitude $||\mathbf{z}||$ and shape z_i of the input drive. For example, we consider a *delocalized* input drive, i.e. $z_i = \frac{z}{\sqrt{N}}$, (the opposite case of a *localized* input drive is discussed in Supplementary Section V C 2 and Figs S6, S7, S8, leading to qualitatively similar results) and find that $\mathrm{Var}[y_i] \approx \frac{\Delta^2 z^2}{2N} G^2(z)$, independent of i. In Figure 4a,b we plot the mean and variance of the neural response for two values of Δ, showing that the analytical approximations agree well with the exact numerical solution (see Fig. S5 for more values of Δ). Finally, by equating the mean and the standard deviation of the response, we find the threshold $\Delta_{loss}(z)$ marking the boundary between the normalized and non-normalized phases as

$$\Delta_{loss}(z) = \frac{\sqrt{2(\sigma^2 + z^2)}}{1 - \sqrt{\sigma^2 + z^2}} \ , \tag{8}$$

The analytical approximation given by Eq. (8) for the function $\Delta_{loss}(z)$, shown in Fig. 5, is in good agreement with the exact numerical estimate. Since $\Delta_{loss}(z) \approx \Delta_{csd}(z)$, Eq. (8) can be used to predict the onset of critical slowing down in the neural dynamics from the magnitude of the *external* input and the strength of the *internal* recurrent weights. On the one hand, when $z \to 1 - \sigma^2 \approx 1$ normalization is enganged robustly and the range of stability of the circuit extends indefinitely. On the other hand, when $z \to 0$ the range of stability is narrowest.

IV. DISCUSSION

We have established, via numerical experiments and analytical calculation, that: *(i)* the nonlinear modulation of recurrent interactions via inhibitory neurons implementing divisive normalization makes neural networks more stable than unmodulated recurrent linear models; *(ii)* the breakdown of normalization, due to substantial recurrent amplification which is not compensated by an equally strong input drive, occurs concomitantly with the onset of critical slowing down in a broad class of random neural networks.

Our results demonstrate that, at low input drives, increasing the recurrent synaptic strength turns the fixed point into a spiral attractor, as indicated by the damped oscillations in Fig. 3c and Fig. S9 (see Supplementary Section V D for details on how to determine the frequency of oscillations). Crucially, the oscillations begin at the same parameter conditions where we observe the loss of normalization and onset of critical slowing down. This suggests a strong link between these phenomena. Consequently, the detection of such recurrence-driven oscillations under a weak input drive could provide an experimental signature of a non-normalized neural circuit nearing a critical transition. For example, experimental evidence suggests that neural circuits in individuals with autism spectrum disorder exhibit both failure of normalization [43, 44] and excess variabilty (i.e., near the tipping point of instability) [45, 46]. Hence, we predict that such neural circuits will also exhibit critical slowing down, which can be measured as the elapsed time to reach steady state. Increased neural variability and noise correlations, measured across trials of same stimulus presentation, are also characteristic markers of critical slowing down (see Supplementary Section V G).

We noticed that, in the whole phase of critical slowing down, the spectrum of the Jacobian contains a large number of zero eigenvalues in the large N limit, corresponding to the emergence of multiple long time scales. Recently, it has been noted [47] that generating many long time scales in linear models requires fine tuning of the recurrent weights. In our model, many long time scales emerge for a broad range of values of the recurrent interaction strength, hence without fine tuning, suggesting that normalization (or other similar forms of multiplicative inhibitory modulation) might be the key mechanism to generate a full spectrum of slow modes in brain dynamics. A comprehensive analysis of the Jacobian's spectrum, including the determination of the volume of zero modes, and the nature of the degenerate attractor will be presented elsewhere.

V. SUPPLEMENTARY METHODS

A. Numerical study of ORGaNICs' fixed-point

To produce Fig. 2 in the main text we simulated an ORGaNICs network comprising $N = 100$ principal neurons with parameters set to $\sigma = 0.1$ and $\tau_y = \tau_a$. For each chosen value of the recurrent interaction strength Δ, we generated an ensemble of 10^4 recurrent connectivity matrices $W = I + K$. This was achieved by first sampling the entries of an auxiliary matrix L from a Gaussian distribution $\mathcal{N}(0, \Delta^2/N)$, and then defining the symmetric interaction matrix $K = (L + L^\top)/2$. This prescription yields a symmetric random matrix K, whose entries are normally distributed according to

$$K_{ij} = \begin{cases} \mathcal{N}\left(\frac{\mu}{N}, \frac{\Delta^2}{N}\right) , & i = j \\ \mathcal{N}\left(\frac{\mu}{N}, \frac{\Delta^2}{2N}\right) , & i \neq j \end{cases} \tag{9}$$

The network dynamics were simulated using the explicit Euler method (starting with a zero initial condition for all the neurons) with time step $dt = 0.05 \times \tau_y$, using a delocalized input drive $\mathbf{z}$ where each component $z_i = z/\sqrt{N}$ (ensuring $||\mathbf{z}|| = z$). We analyzed the steady-state behavior, identifying whether trajectories converged to a stable fixed point, diverged (indicating an unstable fixed point), or entered a limit cycle. For instances resulting in a stable fixed point, we computed the trial-averaged mean response $\mathbb{E}[y_i]$ and its standard deviation $\sqrt{\mathrm{Var}(y_i)}$ across the ensemble. Furthermore, we calculated the Jacobian matrix of the dynamical system at each stable fixed point using automatic differentiation [41]. Finally, as shown in Fig. 2 and Fig. S1, we plotted the mean response and its standard deviation as a function of the input drive z for different values of Δ. These plots are colored based on the average real part of the largest eigenvalue (in units of $1/\tau_y$) of the Jacobian matrix across trials, indicating the slowest mode of the dynamics near the fixed point.

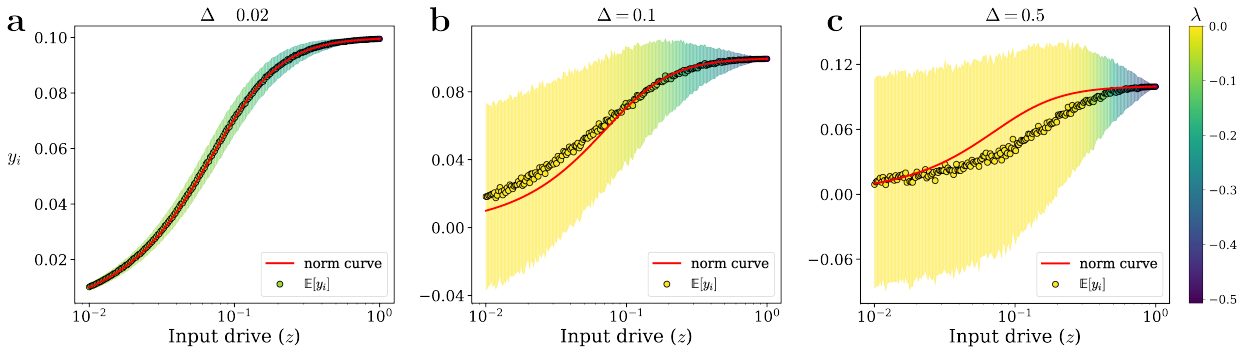

FIG. S1. **Numerical exploration of ORGaNICs' fixed-point statistics.** For each panel, we plot the fixed-point average response $\mathbb{E}[y]$ (dots) and its std. dev. (shaded area) as a function of the normalized input drive z (with $z_i = z/\sqrt{N}$, $N = 100$), for an E:I balanced recurrence matrix K of zero mean and standard deviation Δ, with the same parameters as used in Fig. 2. The solid red curve indicates the normalization equation Eq.(1). The shading color encodes the real part of the largest Jacobian eigenvalue at the fixed point, averaged over samples (always < 0 when convergence is stable). **a,** $\Delta = 0.02$: recurrent interactions are weak, yielding minimal variance around the normalization curve. **b,** $\Delta = 0.1$: moderate recurrence induces variability in the responses across random samples of the recurrent weights at small z, but the mean follows the normalization curve. **c,** $\Delta = 0.5$: strong recurrence dramatically increases the variability at small z; the mean also starts to deviate from the normalization curve.

B. Finite size analysis of the distribution $P(\lambda)$

In this section, we investigate systematically the finite size behavior of the distribution of the largest eigenvalue of the Jacobian at the fixed point $P(\lambda)$. In Fig. S2 we show $P(\lambda)$ for several values of N and Δ. At fixed Δ, we find that $P(\lambda)$ becomes sharply peaked as N increases and tends to a delta function, $P(\lambda) \to \delta(\lambda - \lambda_{gap})$ in the limit $N \to \infty$, where λ_{gap} is nonzero and negative when the circuit is stable (see Fig. S2a) and equal to zero when the circuit is critically slowed down (see Fig. S2b,c,d), i.e.

$$\begin{aligned} \lambda_{gap} < 0 \quad &\to \quad \text{stable} \ , \\ \lambda_{gap} = 0 \quad &\to \quad \text{critical slowing down} \ . \end{aligned} \tag{10}$$

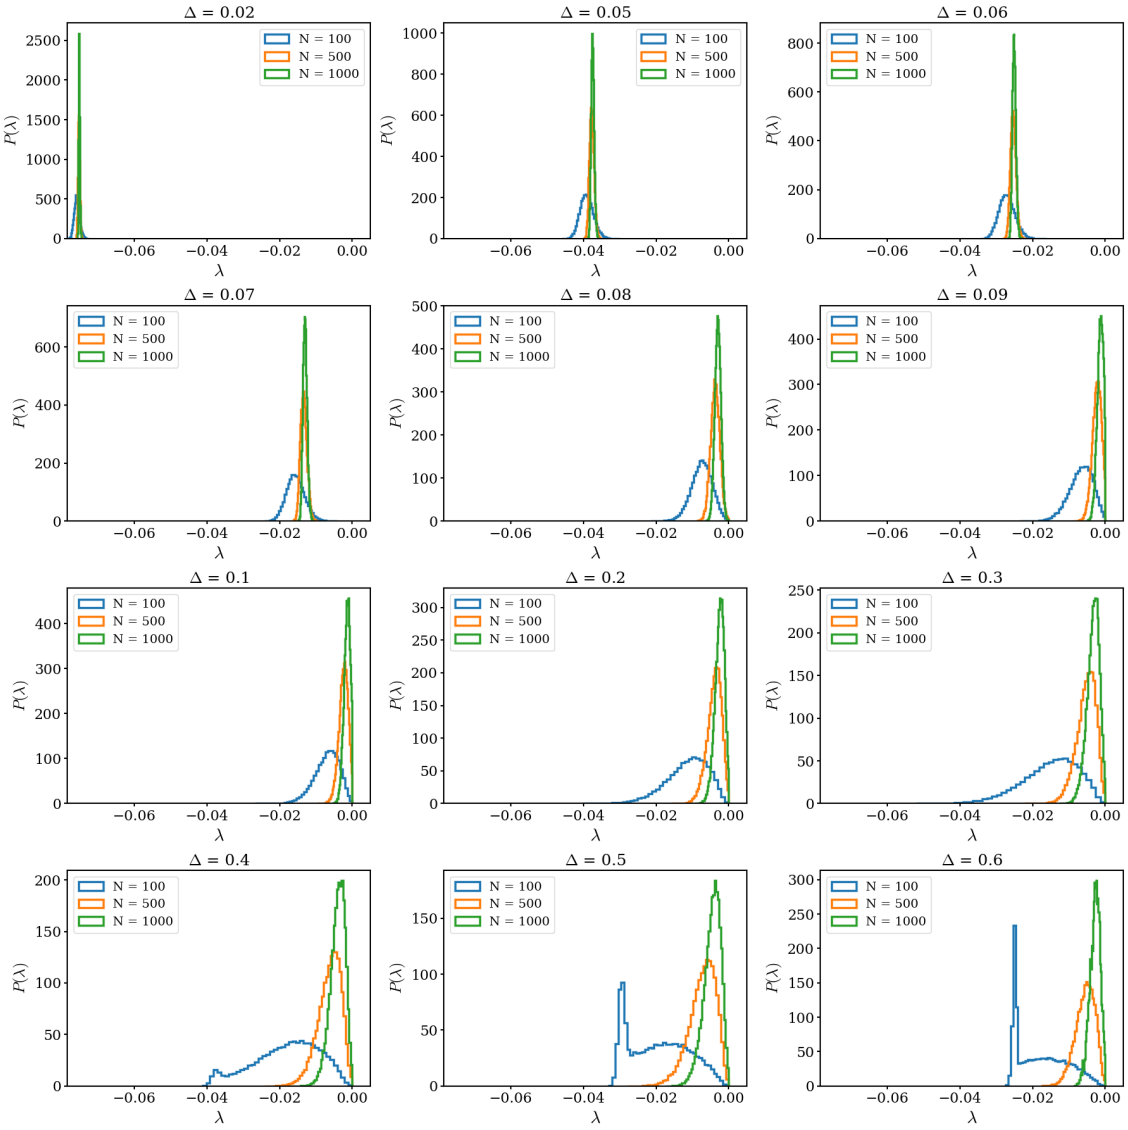

FIG. S2. **Distribution of the Jacobian's largest eigenvalue (λ) for varying system sizes (N).** Distribution of the largest eigenvalue of the Jacobian at the fixed point computed several values of Δ for different system sizes ($N = 100$, 500 and 1000). The input drive, simulation parameters, and the parameters of ORGaNICs are the same as those used for generating Fig. 3 in the main text. Each panel plots the distribution for different values of Δ. As system size increases, finite-size fluctuations narrow, sharpening the gap edge and more clearly revealing the approach of the rightmost eigenvalue toward zero at $\Delta \approx 0.09$. For $\Delta < \Delta_{csd}$ (panel a), all sizes exhibit a clear gap from zero; for $\Delta \geq \Delta_{csd}$ the largest-N curve touches zero most sharply.

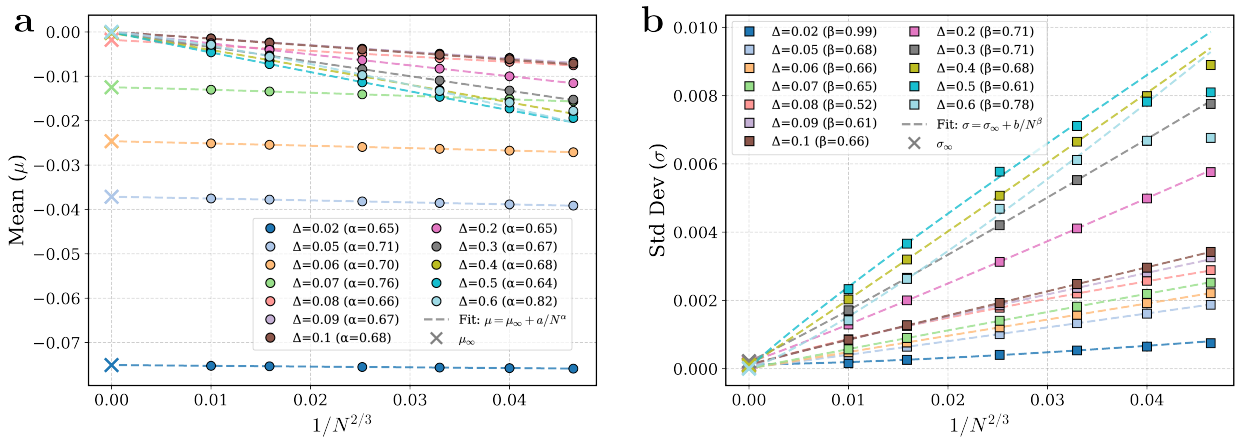

FIG. S3. **Finite size scaling analysis.** The mean and standard deviation of the largest eigenvalue of the Jacobian are shown. The input drive, simulation parameters, and the parameters of ORGaNICs are the same as those used for generating Fig. 3 in the main text. **a,** The mean μ of the largest eigenvalue λ of the Jacobian matrix at the fixed point as a function of $1/N^{2/3}$ for several values of Δ. Dashed lines represent fits following the functional form $\mu = \mu_\infty + a/N^\alpha$, where μ_∞, a, and α are fitting parameters and the fits are performed using the four largest system sizes. The 'x' markers correspond to the extrapolated mean for the infinite system size (μ_∞). The values α in the legend correspond to the fitted slopes and they are close to 2/3 for nearly all values of Δ. μ_∞ vanishes for all values of Δ where we observe critical slowing down ($\Delta \gtrsim 0.09$). **b,** The standard deviation σ of the largest eigenvalue λ of the Jacobian matrix at the fixed point as a function of $1/N^{2/3}$ for several values of Δ. Dashed lines represent fits following the functional form $\sigma = \sigma_\infty + b/N^\beta$, where σ_∞, b, and β are fitting parameters, and fits are performed using the four largest system sizes. The fits extrapolate to a vanishing standard deviation for the infinite system size ($\sigma_\infty \approx 0$), indicating that fluctuations of λ vanish in the thermodynamic limit.

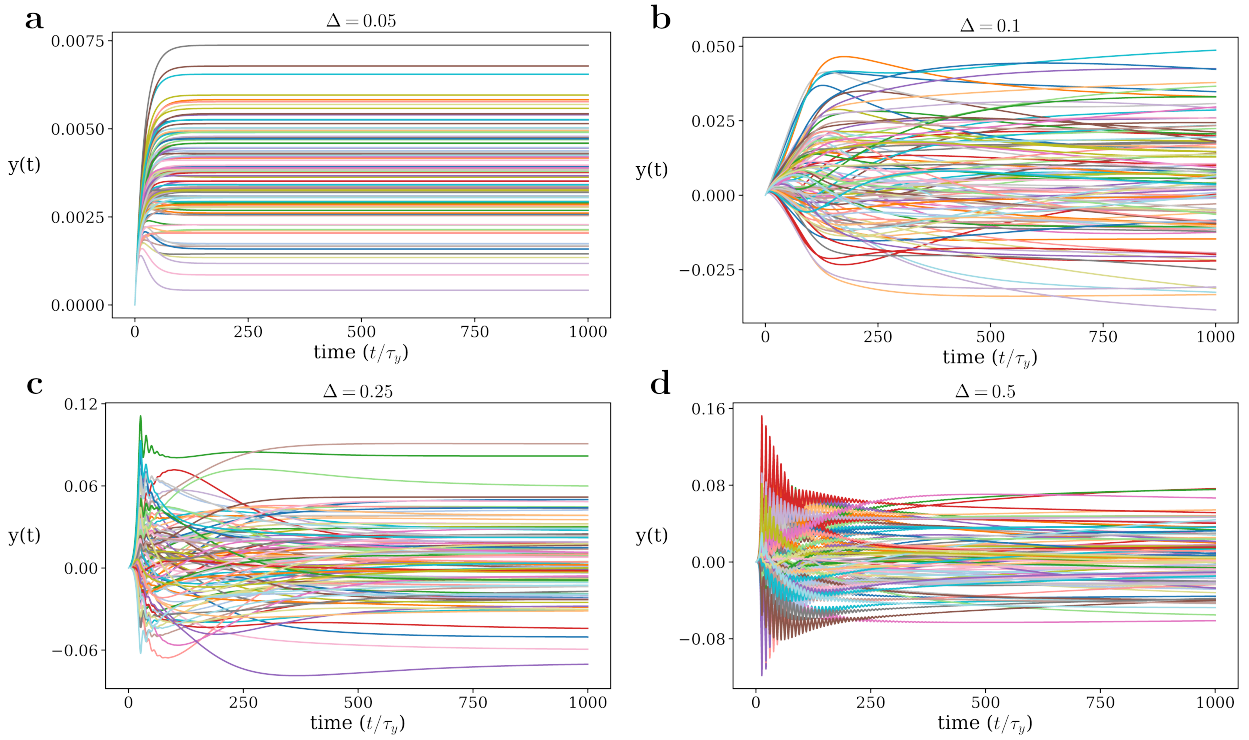

FIG. S4. **Neuronal trajectories for different recurrent synaptic strength Δ.** Each curve traces the time evolution of a distinct principal neuron's response for a given value of Δ (recurrent interaction strength). The input type and the parameters of ORGaNICs are the same as those used for generating Fig. 3 in the main text. We plot the trajectories for 100 neurons selected randomly from the 1000. In the stable regime ($\Delta = 0.05$), trajectories converge rapidly, whereas in the critical-slowing regime ($\Delta = 0.10$, 0.25, and 0.50) convergence is markedly slower.

C. Analytical calculation of the threshold for loss of normalization

Let us consider the ORGaNICs fixed point equations obtained by setting to zero the time derivative in Eq. (3) of the main text:

$$\begin{aligned} y_i &= z_i + (1-\sqrt{a})\sum_{j=1}^{N} W_{ij} y_j \ , \\ a &= \sigma^2 + a\sum_{j=1}^{N} y_j^2 \ , \end{aligned} \tag{11}$$

where we used the fact that firing rates are related to membrane potentials via

$$\begin{aligned} y_i^+ &= \lfloor y_i \rfloor^2 \ , \\ a^+ &= \sqrt{\lfloor a \rfloor} \ , \end{aligned} \tag{12}$$

and we further assumed that $a \geq 0$, which can be checked *a posteriori* to always hold true. To expand around the identity matrix we set

$$W = I + K \ , \tag{13}$$

where K is a small correction. The conditions under which the perturbation K can be considered small with respect to the identity will be deduced later on in our calculation. Inserting Eq. (13) into Eq. (11) we obtain

$$\begin{aligned} \sqrt{a} y_i &= z_i + (1-\sqrt{a})\sum_{j=1}^{N} K_{ij} y_j \ , \\ a &= \frac{\sigma^2}{1-||\mathbf{y}||^2} \ , \end{aligned} \tag{14}$$

where we defined the squared norm as $||\mathbf{y}||^2 = \sum_{j=1}^{N} y_j^2$. We look for a solution to Eq. (14) in the form of a series

$$\begin{aligned} y_i &= y_i^{(0)} + y_i^{(1)} + y_i^{(2)} + \cdots \ , \\ a &= a^{(0)} + a^{(1)} + a^{(2)} + \cdots \ , \end{aligned} \tag{15}$$

where $y_i^{(1)}, a^{(1)}$ are of the same order of magnitude of the perturbation K, the quantities $y_i^{(2)}, a^{(2)}$ are of second order, and so on. To find the first approximation, we substitute $y_i = y_i^{(0)} + y_i^{(1)}$ and $a = a^{(0)} + a^{(1)}$ in Eq. (14) and we keep only terms up to the first order, thus obtaining

$$\begin{aligned} y_i^{(0)} + y_i^{(1)} &= z_i + \left(1-\sqrt{a^{(0)}}\right) y_i^{(0)} + \left(1-\sqrt{a^{(0)}}\right)\left(y_i^{(1)} + \sum_j K_{ij} y_j^{(0)}\right) - \frac{y_i^{(0)} a^{(1)}}{2\sqrt{a^{(0)}}} \ , \\ a^{(0)} + a^{(1)} &= \frac{\sigma^2}{1-||\mathbf{y}^{(0)}||^2} + 2\sigma^2 \frac{\mathbf{y}^{(0)} \cdot \mathbf{y}^{(1)}}{\left(1-||\mathbf{y}^{(0)}||^2\right)^2} \ , \end{aligned} \tag{16}$$

where $\mathbf{y}^{(0)} \cdot \mathbf{y}^{(1)} = \sum_i y_i^{(0)} y_i^{(1)}$ is the usual dot product. Equating the terms of order zero on both sides of Eq. (16) we obtain

$$\begin{aligned} y_i^{(0)} &= \frac{z_i}{\sqrt{a^{(0)}}} \ , \\ a^{(0)} &= \frac{\sigma^2}{1 - ||\mathbf{y}^{(0)}||^2} \ , \end{aligned} \tag{17}$$

which, as it should, is equivalent to the normalization equation

$$\begin{aligned} y_i^{(0)} &= \frac{z_i}{\sqrt{\sigma^2 + ||\mathbf{z}||^2}} \ , \\ a^{(0)} &= \sigma^2 + ||\mathbf{z}||^2 \ . \end{aligned} \tag{18}$$

To find the first order corrections $y_i^{(1)}$ and $a^{(1)}$ we equate the terms of order one on both sides of Eq. (16) and we get

$$\begin{aligned} y_i^{(1)} \sqrt{a^{(0)}} &= \left(1 - \sqrt{a^{(0)}}\right) \sum_j K_{ij} y_j^{(0)} - \frac{y_i^{(0)} a^{(1)}}{2\sqrt{a^{(0)}}} \ , \\ a^{(1)} &= 2a^{(0)} \frac{\mathbf{y}^{(0)} \cdot \mathbf{y}^{(1)}}{1 - ||\mathbf{y}^{(0)}||^2} \ , \end{aligned} \tag{19}$$

where in the equation for $a^{(1)}$ we have used the definition of $a^{(0)}$ given in Eq. (17). To solve Eq. (19) we multiply the first equation by $y_i^{(0)}$ and, after summing over i, we find

$$\mathbf{y}^{(0)} \cdot \mathbf{y}^{(1)} = \frac{\sigma^2 \left(1 - \sqrt{\sigma^2 + ||\mathbf{z}||^2}\right)}{\left(\sigma^2 + ||\mathbf{z}||^2\right)^{5/2}} \mathbf{z}^\top K \mathbf{z} \ , \tag{20}$$

from which we can compute $a^{(1)}$. Substituting this result into Eq. (19) we can express $y_i^{(1)}$ as a function of z and K as

$$\boxed{\begin{aligned} y_i^{(1)} &= G(||\mathbf{z}||) \left(\sum_j K_{ij} z_j - z_i \frac{\mathbf{z}^\top K \mathbf{z}}{\sigma^2 + ||\mathbf{z}||^2} \right) \ , \\ G(||\mathbf{z}||) &= \frac{1 - \sqrt{\sigma^2 + ||\mathbf{z}||^2}}{\sigma^2 + ||\mathbf{z}||^2} \end{aligned}} \tag{21}$$

Having found the general form of the first order correction, we move next to consider the case of a random matrix K sampled from the so-called Gaussian Orthogonal Ensemble (GOE).

We consider the ensemble of symmetric random matrices K, whose entries are normally distributed according to

$$K_{ij} = \begin{cases} \mathcal{N}\left(\frac{\mu}{N}, \frac{\Delta^2}{N}\right) \ , & i = j \\ \mathcal{N}\left(\frac{\mu}{N}, \frac{\Delta^2}{2N}\right) \ , & i \neq j \end{cases} \tag{22}$$

We can compute the average of $y_i^{(1)}$ in Eq.(21) straightforwardly and find

$$\mathbb{E}\big[y_i^{(1)}\big] = \frac{\mu}{N} G(||\mathbf{z}||) \left[\sum_j z_j - \frac{z_i}{\sigma^2 + ||\mathbf{z}||^2} \Big(\sum_j z_j \Big)^2 \right] . \tag{23}$$

A little bit of algebra yields the following expression for the second moment

$$\begin{aligned}
\mathbb{E}\big[\big(y_i^{(1)}\big)^2\big] &= G^2(||\mathbf{z}||) \left[Q_i - \frac{2z_i}{\sigma^2 + ||\mathbf{z}||^2} P_i + \frac{z_i^2}{\big(\sigma^2 + ||\mathbf{z}||^2\big)^2} R \right] , \\
Q_i &= \frac{\Delta^2}{2N} \Big(z_i^2 + ||\mathbf{z}||^2 \Big) - \frac{\mu^2}{N^2} \left[||\mathbf{z}||^2 - \Big(\sum_j z_j \Big)^2 \right] , \\
P_i &= \frac{\Delta^2}{N} z_i ||\mathbf{z}||^2 - \frac{\mu^2}{N^2} \left[2z_i ||\mathbf{z}||^2 - z_i^3 - \Big(\sum_j z_j \Big)^3 \right] , \\
R &= \frac{\Delta^2}{N} ||\mathbf{z}||^4 - \frac{\mu^2}{N^2} \left[2||\mathbf{z}||^4 - \Big(\sum_j z_j^4 \Big) - \Big(\sum_j z_j \Big)^4 \right] .
\end{aligned} \tag{24}$$

Having found the general expressions for the first and second moments of $y_i^{(1)}$, next we discuss the case $\mu = 0$ (E:I balance), corresponding to having an equal number (on average) of positive and negative synaptic weights. Mathematically, this is obtained by setting to zero the mean ($\mu = 0$) of the random matrix entries K_{ij}. The mean and variance of the perturbation $y_i^{(1)}$ simplify considerably and read

$$\begin{aligned}
\mathbb{E}\big[y_i^{(1)}\big] &= 0 , \\
\mathbb{E}\big[\big(y_i^{(1)}\big)^2\big] &= G^2(||\mathbf{z}||) \left[\frac{\Delta^2}{2N} \big(z_i^2 + ||\mathbf{z}||^2 \big) - \frac{\Delta^2}{N} \frac{2z_i^2 ||\mathbf{z}||^2}{\sigma^2 + ||\mathbf{z}||^2} + \frac{\Delta^2}{N} \frac{z_i^2 ||\mathbf{z}||^4}{\big(\sigma^2 + ||\mathbf{z}||^2\big)^2} \right] .
\end{aligned} \tag{25}$$

In the following, we will consider two types of input drives, a **delocalized** input drive, characterized by a vector $\mathbf{z}$ with all entries z_i equal to

$$z_i = \frac{z}{\sqrt{N}} \qquad \text{delocalized input drive} , \tag{26}$$

and the case of a **localized** input drive where all entries are equal to zero but one, for example z_1, and denoted

$$z_i = z\delta_{i1} \qquad \text{localized input drive} . \tag{27}$$

1. *Delocalized input drive*

When the input drive is delocalized, the variance of the perturbation becomes

$$\mathbb{E}\big[\big(y_i^{(1)}\big)^2\big] = \frac{\Delta^2 z^2}{2N} G(||\mathbf{z}||)^2 + O(N^{-2}) . \tag{28}$$

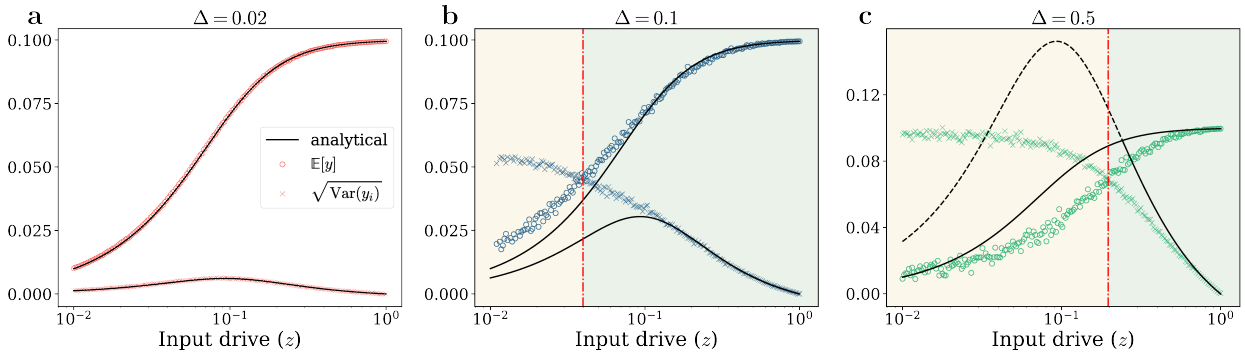

FIG. S5. **Loss of normalization.** Following the analysis presented in Fig. 4, this figure illustrates the mean (circles) and standard deviation (crosses) of the fixed point neural responses versus the input norm z for three additional values of the recurrent interaction strength: $\Delta = 0.02$, $\Delta = 0.1$, and $\Delta = 0.5$. The network consists of $N = 100$ neurons, and each point is found using 1000 realizations. **a,** $\Delta = 0.02$, the std. dev. remains below the mean across all input drives, indicating preserved normalization. **b,** $\Delta = 0.1$ and **c,** $\Delta = 0.5$, the std. dev. exceeds the mean at small z, demonstrating loss of normalization, defined by the crossing point (dashed red line). The theoretical predictions from perturbation theory (black curves) match the numerical simulations well in the normalized regime (mean $>$ std. dev.). Discrepancies increase at small z for larger Δ, where normalization is lost.

The threshold $\Delta_{loss}(z)$ separating the phase where responses are normalized from the phase where they are not is obtained by equating the mean of the response $\mathbb{E}[y_i]$ to its standard deviation $\sqrt{\text{Var}[y_i]}$, yielding

$$1 = \frac{\mathbb{E}[y_i]}{\sqrt{\text{Var}[y_i]}} = \frac{y_i^{(0)}}{\sqrt{\mathbb{E}\left[\left(y_i^{(1)}\right)^2\right]}} \quad \rightarrow \quad \frac{z}{\sqrt{N}} \frac{1}{\sqrt{\sigma^2 + z^2}} = \frac{\Delta z}{\sqrt{2N}} G(||\mathbf{z}||) \ , \tag{29}$$

from which we obtain

$$\frac{\Delta_{loss}(z)}{\sqrt{2}} = \frac{\sqrt{\sigma^2 + z^2}}{1 - \sqrt{\sigma^2 + z^2}} \ , \tag{30}$$

which is Eq. (8) in the main text. In Fig. S5 we compare the analytical approximations for the mean and variance of the responses with the exact numerical values. The agreement is excellent at small Δ, since the neural responses are always normalized, i.e. normalization always holds. For larger Δ the analytical and numerical results also agree well at large input drive, where the responses are normalized. At small z, normalization breaks down as well as the analytical approximation.

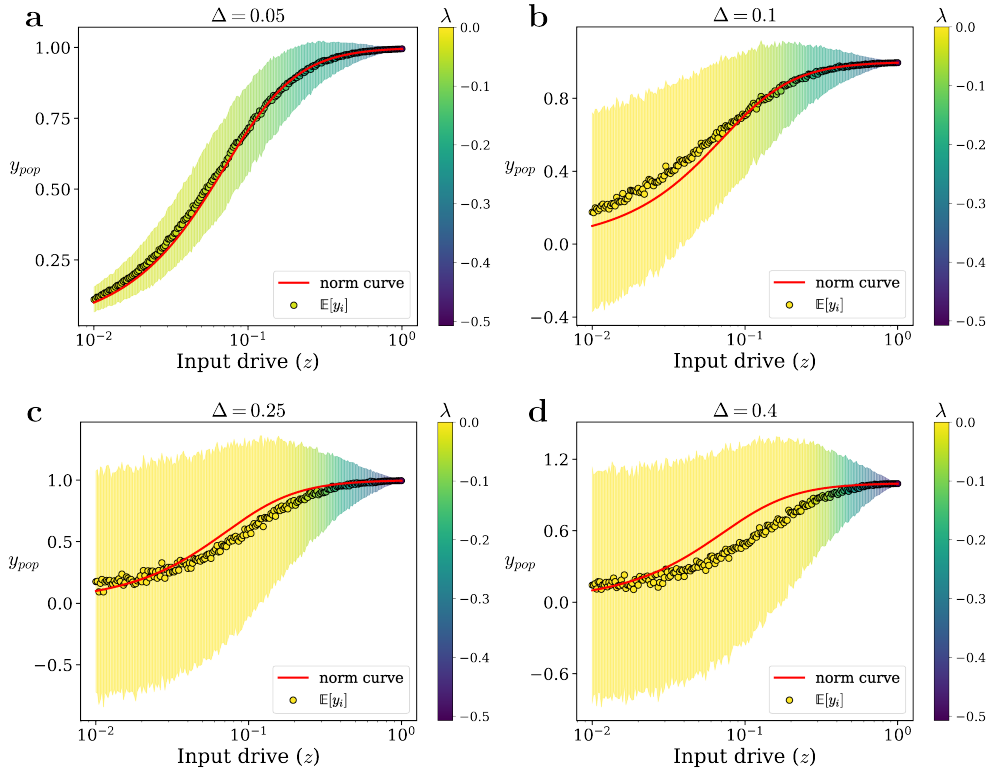

FIG. S6. **Numerical solution of the ORGaNICs' fixed point equations for localized input drive. a,** Fixed-point average response $\mathbb{E}[y_{pop}]$, defined in Eq. (32), as a function of the input drive z (chosen as $z_i = z\delta_{1i}$) for an E:I balanced recurrence matrix K with zero mean and recurrent interaction strength $\Delta = 0.05$ and $N = 100$ neurons, obtained by solving numerically Eq. (3) using the explicit Euler method with time step $dt = 0.05 \times \tau_y$. The semisaturation constant is $\sigma = 0.1$ and the time constants $\tau_y = \tau_a$. Each point is an average over 1000 realizations of the synaptic weights K_{ij}. The neural responses still follow, on average, the normalization Eq. (1) (solid red curve), but pick up a variance in presence of recurrent connections, represented by the shaded area around the data points. The color code of the shaded area represents the real part of the largest eigenvalue of the Jacobian at the fixed point averaged over samples, whose value is well below 0 for all z. **b, c, d** For $\Delta = 0.1, 0.25, 0.4$ the average response is still normalized, but the variance is bigger than in (**a**). For sufficiently small input drives, the largest eigenvalue of the Jacobian at the fixed point vanishes and, as a consequence, convergence to the fixed point occurs on long time scales, a phenomenon known as critical slowing down.

2. Localized input drive

In this section, we show that our results and conclusions are the same for the localized input. We consider the extreme case where **z** is a one-hot vector with

$$z_i = z\delta_{i1} \ . \tag{31}$$

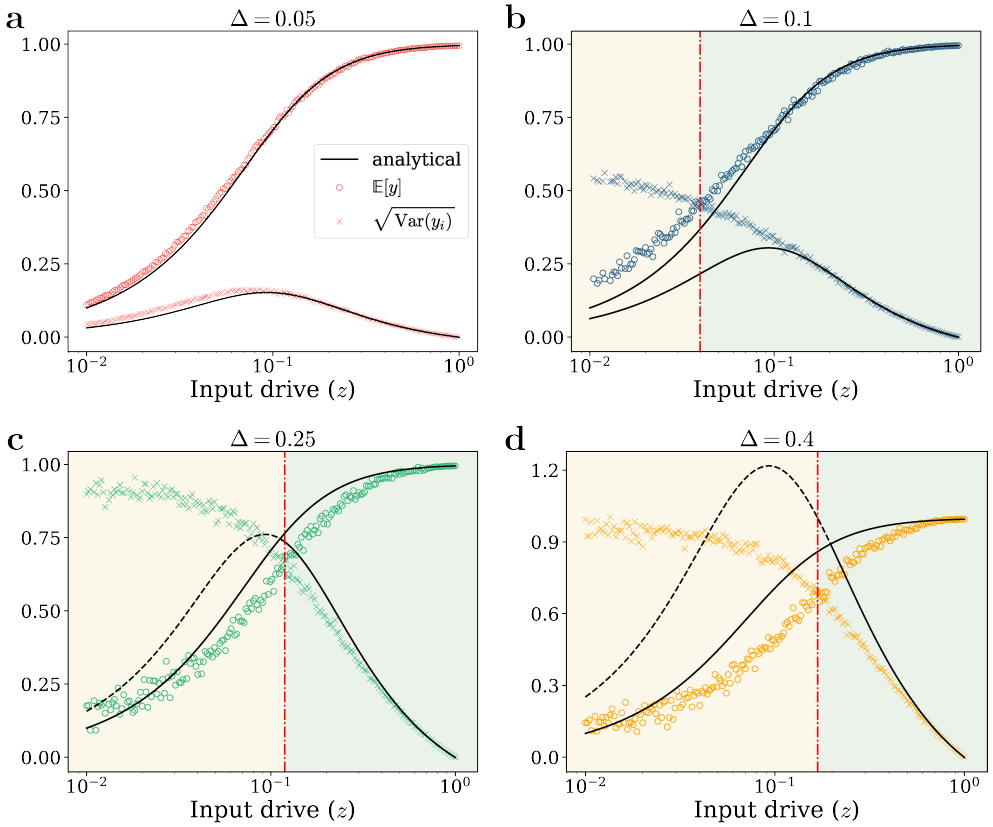

FIG. S7. **Loss of normalization for localized input drive. a,** Mean (circles) and standard deviation (crosses) of the fixed point response y_{pop}, defined in Eq. (32), as a function of the norm z of the localized input drive $z_i = z\delta_{1i}$ for an E:I balanced recurrence matrix K with zero mean and recurrent interaction strength $\Delta = 0.05$. We used $N = 100$ neurons and averaged over 10^3 realizations of the random matrix K. The analytical approximations (solid curves) for the mean Eq. (33) and standard deviation Eq. (34) of the response, computed with perturbation theory, show a good agreement between the theoretical and numerical solutions. In this case the standard deviation is smaller than the mean for all values of z, so the neural responses are always normalized. **b, c, d** Same as in **a**, but using $\Delta = 0.1, 0.25, 0.4$. The standard deviation is smaller than the mean at large input drive, but gets bigger than the mean at small input drive. The value of z where the two curves cross each other, given by Eq. (37), defines the point at which the neural responses lose normalization. The analytical approximations are in good agreement with numerical simulations for almost all values of the input drive (notice the log scale on the abscissa), but become less accurate at small z where the responses are non-normalized.

Since the fixed point y_i depends on i we consider the sum over all responses y_{pop} defined as

$$y_{pop} = \sum_{i=1}^{N} y_i \approx \sum_{i=1}^{N} y_i^{(0)} + y_i^{(1)} \ . \tag{32}$$

The mean of y_{pop} is simply

$$\mathbb{E}[y_{pop}] = \frac{z}{\sqrt{\sigma^2 + z^2}} \ . \tag{33}$$

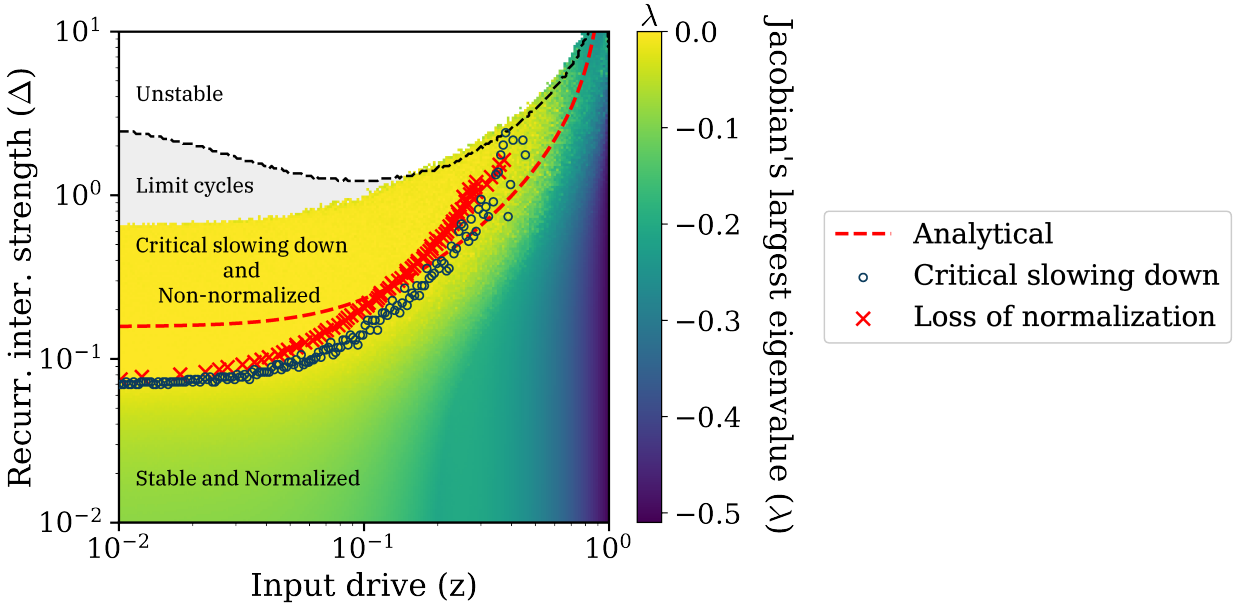

FIG. S8. **Loss of normalization predicts the onset of critical slowing down for localized input drive.** Real part of the largest eigenvalue of the Jacobian at the fixed point in the (z, Δ) plane obtained by solving numerically Eqs. (3) with a localized input drive, i.e., $z_i = z\delta_{i1}$. The parameters of ORGaNICs are the same as those used for generating Fig. 5 in the main text. Color represents the maximum value of λ across 100 trials. Circuits with small Δ are stable at any value of the input drive z and converge quickly to their fixed point, as indicated by a strictly negative eigenvalue $\lambda < 0$. Conversely, for $\Delta_{csd} < \Delta < \Delta_c$, the circuits exhibit critical slowing down, in that they approach the fixed point very slowly, as indicated by the zero eigenvalue, $\lambda = 0$. The onset of critical slowing down is defined by the first time the eigenvalue becomes zero, here denoted by the blue empty circle. The onset of slowing down is equally well captured by the red crosses, representing the boundary between the normalized and non-normalized phases. Loss of normalization is a good proxy for critical slowing down even for localized input drives. For sufficiently large Δ the circuits exhibit limit cycles and for even larger Δ they eventually become unstable, where instability is defined as trajectories diverging in at least 50% of trials.

The variance is given by

$$\mathrm{Var}[y_{pop}] = \mathbb{E}\big[\big(y_1^{(1)}\big)^2\big] + 2\sum_{i\neq 1}\mathbb{E}\big[y_1^{(1)}y_i^{(1)}\big] + \sum_{i,j\neq 1}\mathbb{E}\big[y_i^{(1)}y_j^{(1)}\big]\ . \tag{34}$$

The calculation of the expectation values gives

$$\begin{aligned}
\mathbb{E}\big[\big(y_1^{(1)}\big)^2\big] &= \frac{\Delta^2 z^2}{N} G^2(||\mathbf{z}||)\left(1 - \frac{z^2}{\sigma^2 + z^2}\right)^2 + O(N^{-2})\ , \\
\mathbb{E}\big[y_1^{(1)}y_i^{(1)}\big] &= 0 \quad \text{for } i \neq 1\ , \\
\mathbb{E}\big[y_i^{(1)}y_j^{(1)}\big] &= \begin{cases} \frac{\Delta^2 z^2}{2N} G^2(||\mathbf{z}||) + O(N^{-2}) & \text{for } i, j \neq 1 \\ 0 & \text{for } i = 1 \text{ or } j = 1\ . \end{cases}
\end{aligned} \tag{35}$$

Inserting the previous expressions in Eq. (34) and keeping only the leading order in N we find

$$\mathrm{Var}[y_{pop}] = \frac{\Delta^2 z^2}{2} G^2(||\mathbf{z}||) \ . \tag{36}$$

Equating the mean and standard deviation of y_{pop} we find the $\Delta_{loss}(z)$ as

$$\frac{\mathbb{E}[y_{pop}]}{\sqrt{\mathrm{Var}[y_{pop}]}} = 1 \ \rightarrow \ \frac{\Delta_{loss}(z)}{\sqrt{2}} = \frac{\sqrt{\sigma^2 + z^2}}{1 - \sqrt{\sigma^2 + z^2}} \ , \tag{37}$$

which is the same expression as in Eq. (30).

D. Frequency of oscillations

To understand how the interplay between external stimuli and recurrent drive affects the dynamics of ORGaNICs, we investigated the system's propensity to oscillate under varying conditions. Specifically, we explored the influence of the overall input drive z and the recurrent interaction strength Δ. We systematically varied these two parameters and computed the average oscillation frequency of the network activity as the mean imaginary part of the Jacobian eigenvalues $\mathrm{Im}(\lambda_{\mathbf{J}})/(2\pi)$ evaluated at the system's fixed point. Oscillatory dynamics (spiralling fixed points) are indicated by complex eigenvalues. Fig. S9 shows the resulting heat map in the (z, Δ) plane, where we plot the mean oscillation frequency for a network of $N = 100$ neurons with time constants $\tau_y = \tau_a = 2$ msec, considering both delocalized (Fig. S9a) and localized input drives (Fig. S9b).

We find distinct dynamical regimes. When the input drive and the synaptic strength are weak, i.e., $z \lesssim 0.1$ and $\Delta \lesssim 0.1$, the circuits settle into a stable, non-oscillating fixed point. However, as the input drive increases ($z \gtrsim 0.1$), the fixed point becomes a spiral attractor, leading to oscillations falling within the gamma frequency range (30-100 Hz). Within this regime, the frequency of these input-driven oscillations scales positively with the input drive z (Fig. S9d). A different scenario unfolds when the recurrent synaptic strength is increased (Fig. S9c). For low input drive ($z \lesssim 0.1$), damped oscillations emerge beyond $\Delta \approx 0.1$. In this recurrence-driven regime, the oscillation frequency increases monotonically with Δ from 0 Hz to 80 Hz, before the attractor ultimately turns into limit cycles at higher Δ. These findings highlight the dual roles of external input and internal recurrent drive in shaping the frequency of the oscillatory behavior in ORGaNICs.

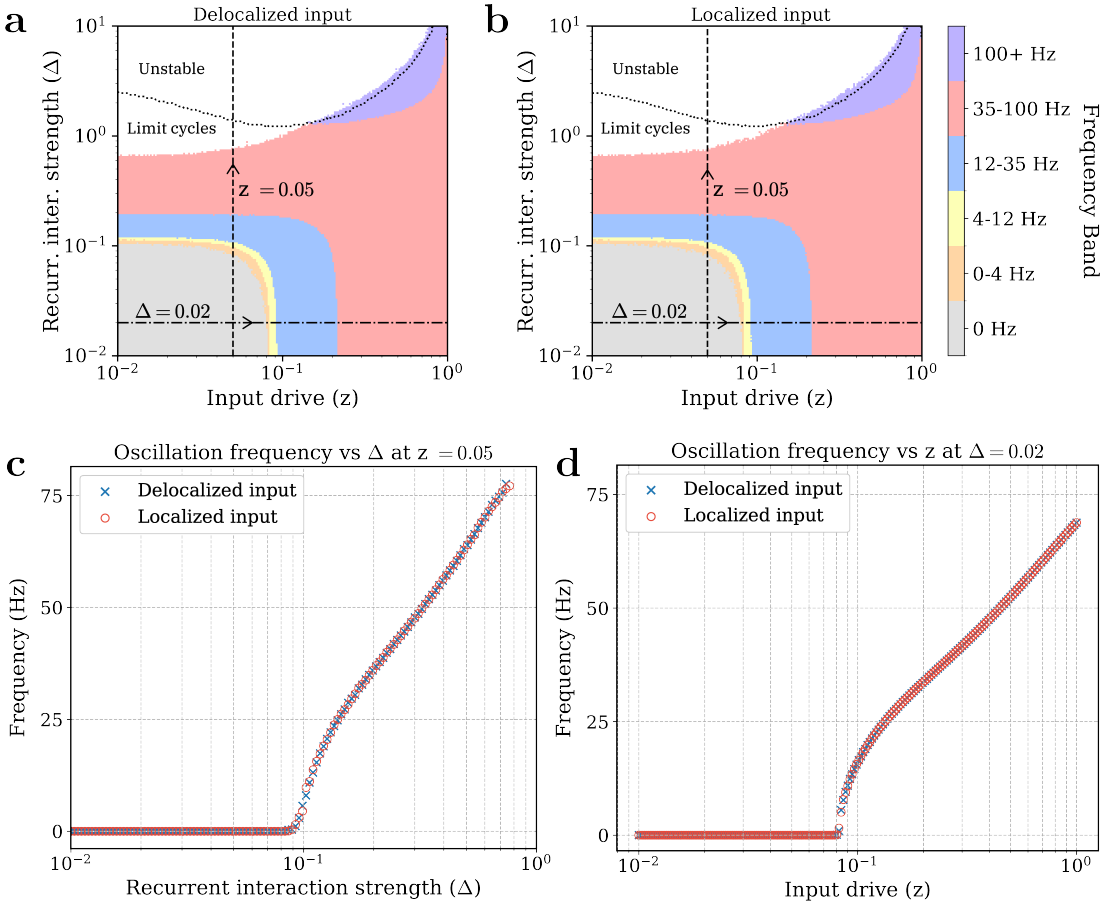

FIG. S9. **Phase diagram and oscillation frequencies in ORGaNICs.** **a**, **b**, Phase diagrams depicting the average oscillation frequency for ORGaNICs as a function of input drive (z) and recurrent interaction strength (Δ). Frequency is color-coded according to standard bands (see color bar: 0 Hz, 0-4 Hz, 4-12 Hz, 12-35 Hz, 35-100 Hz, 100+ Hz), calculated as the mean imaginary part of the Jacobian eigenvalues $\mathrm{Im}(\lambda_{\mathbf{J}})/(2\pi)$ across trials. Results are shown for delocalized (**a**) and localized (**b**) inputs in a system with $N = 100$ neurons, semisaturation constant $\sigma = 0.1$, and time constants $\tau_y = \tau_a = 2$ msec. Dotted curves indicate the transition from limit cycles to an unstable regime, where instability is defined as trajectories diverging in at least 50% of trials. **c**, Oscillation frequency vs recurrent interaction strength (Δ) at a fixed input drive $z = 0.05$. **d**, Oscillation frequency vs input drive (z) at a fixed recurrent interaction strength $\Delta = 0.02$. Plots **c** and **d** compare delocalized (blue circles) and localized (red circles) inputs, showing minimal difference between the two input types.

E. ORGaNICs with alternative activation functions

We consider the effect of changing the activation function, which determines the firing rates (y^+) from the membrane potentials (y) of the principal neurons. In the model studied in the main text we use a quadratic activation function $y^+ = y^2$ (see phase diagram of stability in Fig. S10a). Here, we investigate two alternative models incorporating rectification in the activation function,

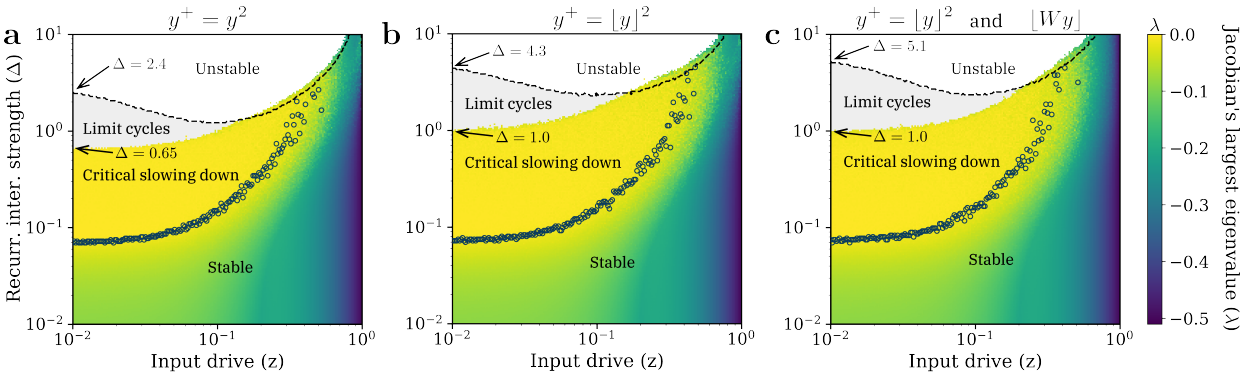

FIG. S10. **Effect of rectification on network stability.** Phase diagram in the parameter space of input drive z and recurrent interaction strength Δ (mesh size 200×200). Color represents the maximum value (across 100 trials) of the Jacobian's eigenvalue with the largest real part (λ). The input type and the parameters of ORGaNICs are the same as those used for generating Fig. 5 in the main text. The panels correspond to: **a**, Model with quadratic activation ($y^+ = y^2$), identical to the phase diagram in Fig. 5. **b**, Model with rectification in the activation function ($y^+ = \lfloor y \rfloor^2$, Eq. 38). **c**, Model with rectification applied in both the activation function and after the recurrent summation ($y^+ = \lfloor y \rfloor^2$ and $\lfloor Wy \rfloor$ term, Eq. 39). We observe that the boundaries marking the transition from critical slowing down to limit cycles, and from limit cycles to unstable dynamics (indicated by dashed curves), shift upwards in going from **a** to **b** to **c**.

defined as $\lfloor x \rfloor = \max(0, x)$, a common choice known as ReLU in artificial neural networks.

First, we introduce rectification such that the firing rate is calculated as $y^+ = \lfloor y \rfloor^2$. This gives us the following dynamical system (see phase diagram in Fig. S10b):

$$\begin{cases} \tau_y \dot{y_i} = -y_i + z_i + (1 - a^+) \sum_{j=1}^{N} W_{ij} \lfloor y \rfloor_i \\ \tau_a \dot{a} = -a + \sigma^2 + \left(\sum_{i=1}^{N} y_i^+ \right) a \ , \end{cases} \tag{38}$$

In the second model, we explore a different placement for rectification. While still using the rectified firing rate $y^+ = \lfloor y \rfloor^2$, we apply rectification after the weighted recurrent inputs have been summed, in the dynamical equation for y. This leads to the following dynamical system (see corresponding phase diagram in Fig. S10c):

$$\begin{cases} \tau_y \dot{y_i} = -y_i + z_i + (1 - a^+) \left\lfloor \sum_{j=1}^{N} W_{ij} y_i \right\rfloor \\ \tau_a \dot{a} = -a + \sigma^2 + \left(\sum_{i=1}^{N} y_i^+ \right) a \ , \end{cases} \tag{39}$$

The model in Eq. (39) is not neurobiologically relevant, but is relevant for designing ML architectures [18].

We analyzed the stability of these models by examining their phase diagrams in the parameter space of input drive (z) and recurrent interaction strength (Δ), shown in Fig. S10. We find that introducing these alternative forms of rectification do not qualitatively change the network's phase diagram. However, the boundaries that mark the transition from critical slowing down to limit cycles, and from limit cycles to unstable dynamics, shift towards larger values of Δ, when going from panel (a) to (b) to (c) of Fig. S10. Therefore, introducing rectification increases the range of parameters for which the neuron's trajectories remain bounded (including the limit cycles regime).

F. E-I imbalanced recurrent networks

In this section, we investigate the impact of excitation-inhibition (E-I) imbalance in the recurrent weight matrix W on the stability of ORGaNICs. We introduce E-I imbalance by setting a non-zero mean μ for the entries of the recurrent connectivity matrix K, such that $K_{ii} \sim \mathcal{N}(\mu/N, \Delta^2/N)$ and $K_{ij} \sim \mathcal{N}(\mu/N, \Delta^2/2N)$ for $i \neq j$. This introduces net inhibition (for $\mu < 0$) or net excitation ($\mu > 0$) in K. We generated phase diagrams, shown in Fig. S11, analogous to Fig. 5 for different values of $\mu = [0.0, 0.05, 0.1, 0.25, 0.5, 1.0, -0.1, -0.5, -1.0]$, using a delocalized input drive $z_i = z/\sqrt{N}$ and network parameters $N = 100$, $\sigma = 0.1$, $\tau_y = \tau_a$. We observe three main things:

1. increasing excitation (larger positive μ) shifts the onset of critical slowing down towards larger values of the recurrent interaction strength Δ. For strong excitatory imbalance (e.g., $\mu = 1.0$), the network transitions from the stable regime to the limit cycle regime at small input drive z without undergoing critical slowing down;

2. increasing inhibition (larger negative μ) makes the circuit operate in the critically slowed down regime for larger values of Δ at any input drive z. For strong inhibitory imbalance (e.g., $\mu = -1.0$), the circuit remains stable across all z without entering into limit cycles at small z;

3. most importantly, the loss of normalization is still a good predictor of the onset of critical slowing down across all values of μ.

We also examined how E-I imbalance affects the oscillation frequencies in ORGaNICs (Fig. S12). Upon increasing excitation ($\mu > 0$), the region exhibiting high-frequency oscillations (gamma band

and higher) expands. For strong excitation (e.g., $\mu = 1.0$), the network tends to oscillate at high frequencies across a wider range of Δ and z values. This suggests that net excitation in the recurrent connections promotes faster oscillations. On the contrary, increasing inhibition (Fig. S12g,h,i) ($\mu < 0$) promotes slower oscillations, especially at large input drives.

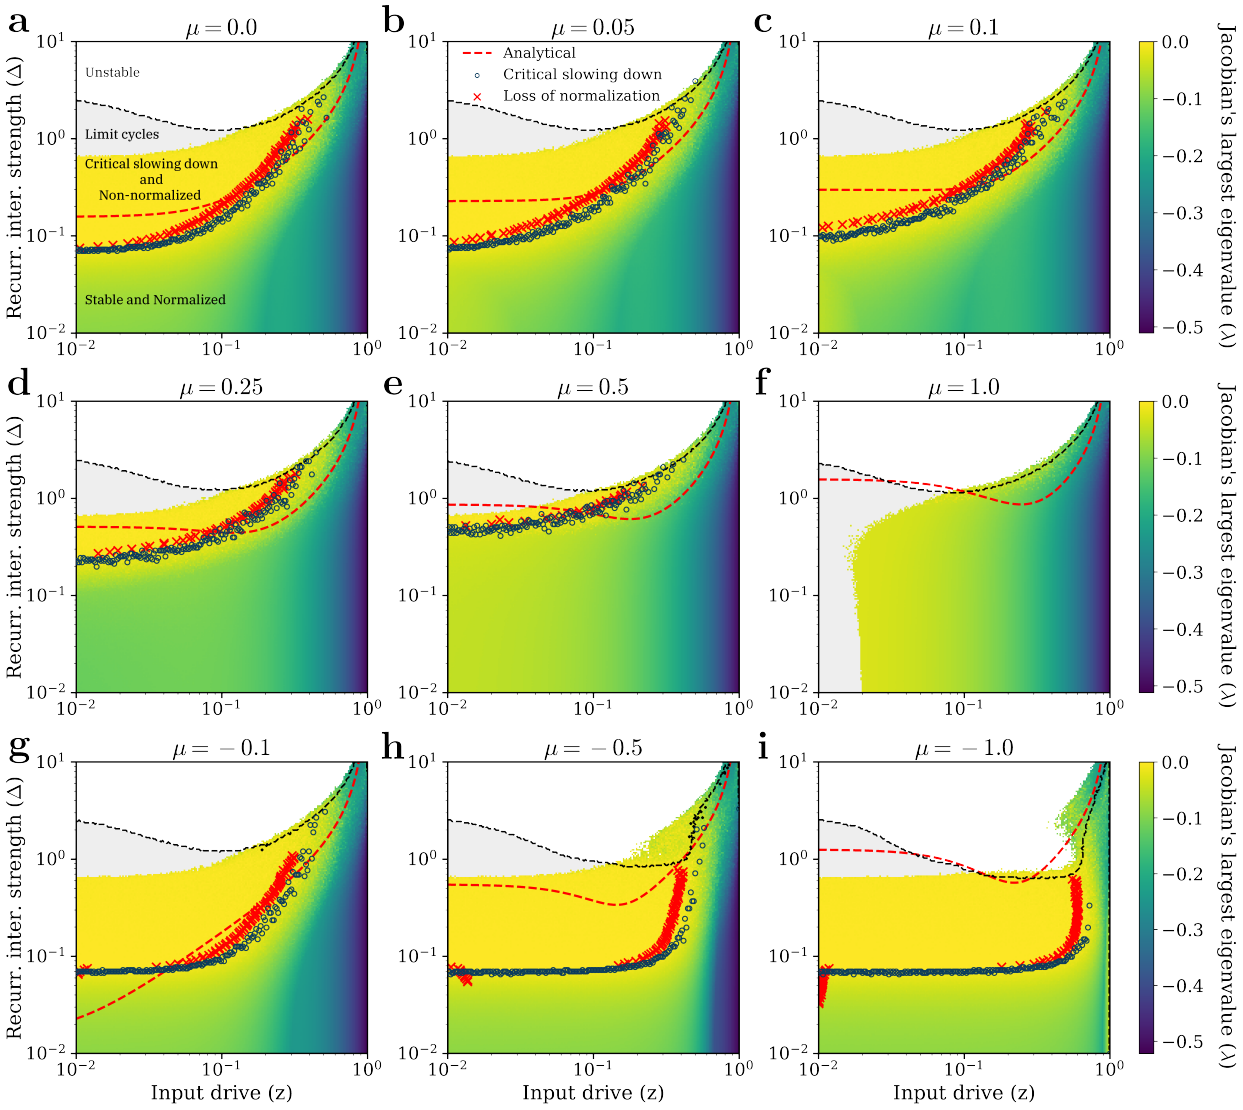

FIG. S11. **Effect of E-I imbalanced recurrence on stability.** Phase diagrams showing the real part of the largest eigenvalue λ of the Jacobian at the fixed point in the (z, Δ) plane for varying levels of E-I imbalance, controlled by the mean μ of the recurrent weights K_{ij}. Each panel corresponds to a different value of μ (see discussion in the text): **a,** $\mu = 0.0$ (balanced, identical to Fig. 5); excess excitation: **b,** $\mu = 0.05$, **c,** $\mu = 0.1$, **d,** $\mu = 0.25$, **e,** $\mu = 0.5$, **f,** $\mu = 1.0$; excess inhibition: **g,** $\mu = -0.1$, **h,** $\mu = -0.5$, **i,** $\mu = -1.0$. Color represents the maximum λ across 100 trials (for $N = 100$, $\sigma = 0.1$, $\tau_y = \tau_a$, delocalized input $z_i = z/\sqrt{N}$). Blue open circles mark the numerically determined onset of critical slowing down, while red crosses indicate the numerically determined loss of normalization. The dashed red curves show the analytical prediction for loss of normalization. Dashed black curves delineate boundaries between the limit cycle (gray region) and the unstable (white region) regimes, where instability is defined as trajectories diverging in at least 50% of trials.

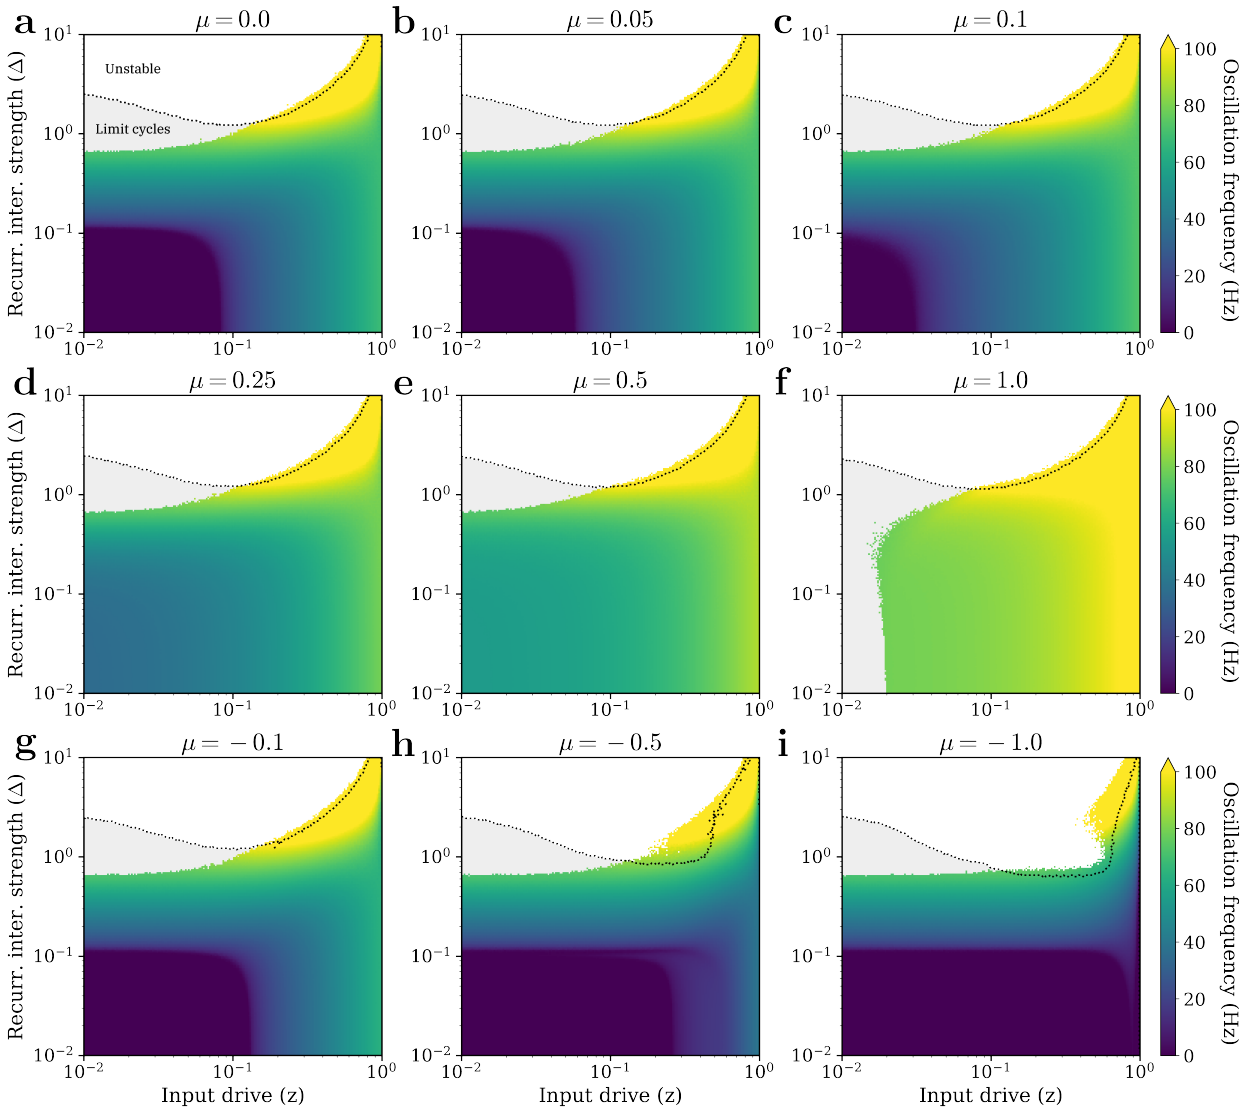

FIG. S12. **Effect of E-I imbalanced recurrence on oscillation frequency.** Phase diagrams depicting the average oscillation frequency (calculated as mean of $\mathrm{Im}(\lambda_J)/(2\pi)$ across trials) as a function of input drive z and recurrent interaction strength Δ for varying levels of E-I imbalance μ. Parameters are $N = 100$, $\sigma = 0.1$, $\tau_y = \tau_a = 2$ msec, delocalized input $z_i = z/\sqrt{N}$. Panels correspond to: **a,** $\mu = 0.0$; excess excitation: **b,** $\mu = 0.05$, **c,** $\mu = 0.1$, **d,** $\mu = 0.25$, **e,** $\mu = 0.5$, **f,** $\mu = 1.0$; excess inhibition: **g,** $\mu = -0.1$, **h,** $\mu = -0.5$, **i,** $\mu = -1.0$. Dotted black curves delineate boundaries between the limit cycle (gray region) and the unstable (white region) regimes, where instability is defined as trajectories diverging in at least 50% of trials. Overall, increasing excitation ($\mu > 0$) generally promotes higher oscillation frequencies, especially at small input drives. While increasing inhibition ($\mu < 0$) promotes lower oscillation frequencies, especially at large input drives.

G. Effect of critical slowing down on neural variability

A key marker of critical slowing down is a drastic increase in trial-to-trial neural variability and noise correlations between neurons. To illustrate why this occurs, we consider the ORGaNICs model with additive Gaussian white noise in the dynamical system:

$$\begin{cases} \tau_y \dot{y}_i = -y_i + z_i + (1 - a^+) \sum_{j=1}^{N} W_{ij} y_j + \sigma \eta_i(t) \\ \tau_a \dot{a} = -a + \sigma_{ss}^2 + \left(\sum_{i=1}^{N} y_i^+ \right) a + \sigma \eta_a(t) \ , \end{cases} \tag{40}$$

where $\eta_i(t)$ and $\eta_a(t)$ represent uncorrelated Gaussian white noise processes with zero mean and unit variance (i.e., $\mathbb{E}[\eta_k(t)\eta_l(s)] = \delta_{kl}\delta(t-s)$), and σ here denotes the strength of this noise. Note that σ_{ss}^2 is used for the semisaturation constant to avoid confusion with the noise strength σ. This introduction of stochasticity is distinct from the randomness in the recurrent matrix W considered in the main body of the manuscript.

Assuming the dynamical system operates in the vicinity of the stable fixed point (found in both stable and critically slowed-down regimes) and that the noise strength σ is sufficiently small, we can linearize the system around the fixed point. Let $\mathbf{x}$ be the vector of deviations from the fixed point. The linearized system is:

$$\dot{\mathbf{x}}(t) = \mathbf{J}\mathbf{x}(t) + \sigma \boldsymbol{\eta}(t) \ , \tag{41}$$

where $\mathbf{J}$ is the Jacobian matrix evaluated at the fixed point, and $\boldsymbol{\eta}(t)$ is the vector of white noise processes. The steady-state covariance matrix $\mathbf{P} = \mathbb{E}[\mathbf{x}\mathbf{x}^\top]$ (whose diagonal entries capture trial-to-trial variability and off-diagonal entries capture noise correlations) is given by the solution to the continuous-time Lyapunov equation:

$$\mathbf{J}\mathbf{P} + \mathbf{P}\mathbf{J}^\top + \sigma^2 \mathbf{I} = \mathbf{0} \ , \tag{42}$$

where $\mathbf{I}$ is the identity matrix, and $\sigma^2\mathbf{I}$ is the covariance matrix of the noise term $\sigma\boldsymbol{\eta}(t)$.

Assuming that $\mathbf{J}$ is diagonalizable, we can write its eigendecomposition as $\mathbf{J} = \mathbf{V}\boldsymbol{\Lambda}\mathbf{V}^{-1}$, where $\boldsymbol{\Lambda}$ is a diagonal matrix whose entries λ_i are the eigenvalues of $\mathbf{J}$, and $\mathbf{V}$ is the matrix whose columns are the corresponding eigenvectors. We can transform the coordinates to the eigenbasis of $\mathbf{J}$ by defining $\mathbf{y} = \mathbf{V}^{-1}\mathbf{x}$. The covariance matrix of $\mathbf{y}$ is $\mathbf{M} = \mathbb{E}[\mathbf{y}\mathbf{y}^\top] = \mathbf{V}^{-1}\mathbf{P}(\mathbf{V}^{-1})^\top = \mathbf{V}^{-1}\mathbf{P}\mathbf{V}^{-\top}$. Left-multiplying Eq. (42) by $\mathbf{V}^{-1}$ and right-multiplying by $\mathbf{V}^{-\top}$, we obtain:

$$\mathbf{V}^{-1}\mathbf{J}\mathbf{V}(\underbrace{\mathbf{V}^{-1}\mathbf{P}\mathbf{V}^{-\top}}_{\mathbf{M}}) + (\underbrace{\mathbf{V}^{-1}\mathbf{P}\mathbf{V}^{-\top}}_{\mathbf{M}})\mathbf{V}^\top\mathbf{J}^\top\mathbf{V}^{-\top} + \sigma^2\mathbf{V}^{-1}\mathbf{V}^{-\top} = \mathbf{0} \tag{43}$$

Using $\mathbf{V}^{-1}\mathbf{J}\mathbf{V} = \mathbf{V}^{\top}\mathbf{J}^{\top}\mathbf{V}^{-\top} = \mathbf{\Lambda}$ and defining $\mathbf{B} = \mathbf{V}^{-1}\mathbf{V}^{-\top}$, Eq. (43) becomes:

$$\mathbf{\Lambda}\mathbf{M} + \mathbf{M}\mathbf{\Lambda} + \sigma^2\mathbf{B} = \mathbf{0} \ . \tag{44}$$

This is the Lyapunov equation for the transformed coordinates $\mathbf{y}$. Since $\mathbf{\Lambda}$ is diagonal, we can solve for the entries of $\mathbf{M}$ element-wise:

$$M_{ij}(\lambda_i + \lambda_j) + \sigma^2 B_{ij} = 0 \implies M_{ij} = -\frac{\sigma^2 B_{ij}}{\lambda_i + \lambda_j} \ . \tag{45}$$

Therefore, if the real part of an eigenvalue, say $\mathrm{Re}(\lambda_k)$, approaches zero (which characterizes critical slowing down), the denominator $2\mathrm{Re}(\lambda_k)$ for the diagonal term M_{kk} becomes very small. Assuming B_{kk} (which depends on the eigenvectors) is non-zero, M_{kk} will become very large:

$$M_{kk} = -\frac{\sigma^2 B_{kk}}{2\lambda_k} \ . \tag{46}$$

As $\mathrm{Re}(\lambda_k) \to 0$, the magnitude of M_{kk} tends to infinity. Since the original covariance matrix entries P_{mn} are linear combinations of M_{ij} (as $\mathbf{P} = \mathbf{V}\mathbf{M}\mathbf{V}^{\top}$), a large M_{kk} will typically lead to large entries P_{mn}. This implies increased trial-to-trial variability (large diagonal elements of $\mathbf{P}$) and large noise correlations (large off-diagonal elements of $\mathbf{P}$) when the system is in the critically slowed-down regime compared to the stable and normalized regime.
