Abstract: Gram-negative bacteria release Outer Membrane Vesicles (OMVs) into the extracellular environment. Recent studies recognized these vesicles as vectors to horizontal gene transfer; however, the parameters that mediate OMVs transfer within bacterial communities remain unclear. The present study highlights for the first time the transfer of plasmids containing resistance genes via OMVs derived from Klebsiella pneumoniae (*K. pneumoniae*). This mechanism confers DNA protection, it is plasmid copy number dependent with a ratio of 3.6 times among high copy number plasmid (pGR) versus low copy number plasmid (PRM), and the transformation efficiency was 3.6 times greater. Therefore, the DNA amount in the vesicular lumen and the efficacy of horizontal gene transfer was strictly dependent on the identity of the plasmid. Moreover, the role of *K. pneumoniae*-OMVs in interspecies transfer was described. The transfer ability was not related to the phylogenetic characteristics between the donor and the recipient species. *K. pneumoniae*-OMVs transferred plasmid to Escherichia coli, *Salmonella enterica*, *Pseudomonas aeruginosa* and *Burkholderia cepacia*. These findings address the pivotal role of *K. pneumoniae*-OMVs as vectors for antimicrobial resistance genes spread, contributing to the development of antibiotic resistance in the microbial communities.

Keywords: Outer Membrane Vesicles; *Klebsiella pneumoniae*; horizontal gene transfer; Gram-negative bacteria; DNA

1. Introduction

Horizontal gene transfer (HGT) represents the main source of genetic material transfer among microorganisms [1]. Indeed, HGT provides a driving force for bacterial evolution, increasing bacterial survival, adjustment rate in the harshest environments, and pathogenicity [2–4]. Current knowledge of HGT is based on three widely described mechanisms for the exchange of genetic material between bacteria: transformation, conjugation and transduction [5–7]. Transformation involves the natural uptake of naked DNA from an extracellular environment; this phenomenon occurs when cells are in a physiological state of competence, regulated by 20–50 proteins [8,9]. Conjugation is a DNA transfer mechanism through the sexual pilus and requires cell-to-cell contact [10]. Conjugative systems are frequently associated with plasmid transfer [11]. Transduction entails the transfer of DNA between bacteria through the bacteriophage infections [12]. The recombinant

phage particle can contain up to 100 kilobases of DNA and the infection is limited to host specificity [13]. Recently, several studies reported that HGT processes are facilitated by Outer Membrane Vesicles (OMVs) [14–17].

OMVs are spherical nanostructures, 50–250 nm in diameter, released naturally and constitutively by Gram-negative bacteria during their growth [18]. OMVs originate from the outer membrane and include in the vesicular lumen lipopolysaccharide, peptidoglycan, phospholipids, genetic material (DNA and RNA) and periplasmic and cytoplasmic protein components, during their biogenesis [19]. Although many aspects of vesicular biogenesis and regulation of their composition remain unclear, the biological functions associated with OMVs release have been extensively described [20,21]. These vesicles play a key role in the bacteria–environment, bacteria–bacteria and bacteria–host interactions [22,23]. OMVs are recognized for their role in nutrient acquisition, response to stress, biofilm formation and toxins release, adhesion and virulence factors, and in host defense system evasion [24,25]. OMVs role in HGT was reported in *E. coli*, *Acinetobacter baumannii*, *Acinetobacter baylyi*, *Porphyromonas gingivalis*, *P. aeruginosa* and *Thermus thermophilus* [25–28]. Yaron et al. demonstrated the transfer of virulence genes through *E. coli*-OMVs between bacteria of different species. Moreover, they proved that the genetic material was protected from digestion with DNase, confirming the packaging in the vesicular lumen [29,30]. OMVs derived from *A. baumannii* were also identified as vectors for antibiotic resistance gene transfer. In the study of Rumbo et al., plasmid-borne bla$_{OXA-24}$ gene conferred carbapenems resistance to sensitive Acinetobacter strains [31]. These evidences highlight the potential OMVs contribution to the spread of virulence and antibiotic resistance which represents, to date, a serious risk to human health.

In this scenario, *K. pneumoniae* represents one of the most worrying pathogens involved in nosocomial infections [32]. The constant antibiotics treatment induces selective pressures, causing the evolution of multidrug-resistant (MDR) bacteria [33]. Our previous studies demonstrated that OMVs derived from *K. pneumoniae* play a crucial role in the microorganism–host interaction, modulating miRNAs genetic transcription and influencing the inflammatory response [14,34]. Currently, no study showed the role of *K. pneumoniae*-OMVs as a carrier for HGT, allowing the transport of genetic material and the spread of resistance genes. Therefore, this study demonstrates, for the first time, *K. pneumoniae*-OMVs HGT role. We investigated OMVs contribution in the genetic material cargo and in intra- and inter-species transfer. After, we collected evidence to demonstrate that plasmid copy number (PCN) might play an important role in the biogenesis, cargo and in the HGT mechanisms. Finally, we verified OMVs stability over time and whether storage conditions might influence gene transfer.

2. Results

2.1. Characterization of Isolated K. pneumoniae-OMVs

To purify the OMVs derived from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM, bacteria were grown in LB supplemented with ampicillin up to the late logarithmic-phase of the bacterial growth curve (see Materials and Methods for specifications). Vesicles were collected from culture supernatants and characterized in terms of morphology, size and polydispersity index (PDI). Purified OMVs appeared at TEM as electron-dense particles, with uniform spherical morphology (Figure 1, panel A and B). No bacterial contaminant was visualized, demonstrating the total sterility of the vesicular suspensions used. Dynamic light scattering (DLS) analysis showed that OMVs derived from *K. pneumoniae*-pGR measured a size of 113.8 ± 53.7 nm and were characterized by a slightly heterogeneous size distribution, represented by the PDI of 0.223 (Figure 1C). OMVs purified from *K. pneumoniae*-PRM showed a reduction in size and higher vesicular populations homogeneity, recording a size of 94.13 ± 41.10 nm and a PDI of 0.191 (Figure 1D). Purified OMVs were also characterized based on protein profile. The total vesicular proteins were extracted from *K. pneumoniae*-OMVs via lysis buffer and then quantified by Bradford assay. The protein amount was 35.77 mg and 30.00 mg for *K. pneumoniae*-pGR and *K. pneumoniae*-PRM,

respectively, obtained from 600 mL of culture supernatant. Five micrograms of protein were loaded on 10% SDS-PAGE and the gel was stained with Blue Coomassie (Supplementary Figure S1). The corresponding bands were excised and subjected to in-situ digestion protocols. Peptides were analyzed by high resolution nanoLC- MS/MS. Mass spectra analysis allowed identifying with high confidence proteins common to both purified OMVs samples (Supplementary Table S1). These proteins were classified according to the subcellular localization site and biological function (Figure 2A,B). The vesicles contained 14 membrane-associated proteins (28.57%), 3 periplasmic proteins (6.12%) and 32 cytosolic proteins (65.31%). In addition, 3 DNA-binding proteins (6.12%) were identified among the proteins annotated for their binding function. Twenty-one enzymes were revealed, including 3 oxidoreductases (14.29%), 2 transferases (9.52%), 1 aminopeptidase (4.76%), 5 lyases (23.81%), 2 isomerases (9.52%) and 8 ligases (38.10%) (Figure 2C). To confirm accurate reliability and reproducibility of data, three independent OMVs purifications were performed and analyzed for each strain.

2.2. DNA Packaging in K. pneumoniae OMVs

The propensity of *K. pneumoniae* OMVs to incorporate genetic material during the biogenesis process was evaluated by transforming bacteria with pGR and PRM plasmids. *K. pneumoniae*-pGR and *K. pneumoniae*-PRM were grown on LB supplemented with 100 µg mL^{-1} of ampicillin for selection of transformants. Plasmid DNA extraction and enzymatic digestion profile confirmed the plasmids presence in the bacterial strains (Supplemental Figure S2A,B). The presence of pGR and PRM plasmids in *K. pneumoniae*-OMVs was evaluated by absolute qPCR. To demonstrate that DNA was present in the vesicular lumen and protected from the extracellular nucleases action, qPCR was performed using OMVs samples either treated or untreated with DNase. In untreated OMVs, plasmid concentration was 18.91 ± 0.53 and 14.78 ± 0.91 ng DNA/µg OMVs, for pGR and PRM, respectively. In OMVs treated with DNase before vesicular lysis, pGR recorded a higher loading density, measuring 10.4 ± 0.05 ng DNA/µg OMVs, which corresponded approximately to 1.9×10^9 PCN/µg OMVs. Otherwise, PRM measured a plasmid concentration of 3.08 ± 0.62 ng DNA/µg OMVs, corresponding to 9.6×10^8 PCN/µg OMVs (Figure 3).

OMVs-pGR	Ct	DNA [ng/µL]	PCN
No DNase treat.	16.68	1.49 ± 0.02	2.72×10^8
DNase treat.	18.94	0.83 ± 0.05	1.52×10^8

OMVs-PRM	Ct	DNA [ng/µL]	PCN
No DNase treat.	20.46	1.78 ± 0.02	5.56×10^8
DNase treat.	24.12	0.37 ± 0.62	1.16×10^8

2.3. OMVs Mediate the Plasmid Intraspecies Transfer

Transformation experiments were performed by isolating OMVs from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM. *K. pneumoniae* ATCC recipient cells were incubated with 10 µg of OMVs derived from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM. After 24 h, treated cells were plated on LB-ampicillin agar to detect the plasmid resistance marker in the recipient bacteria. OMVs purified from *K. pneumoniae*-pGR induced a transformation efficiency of $2.8 \pm 0.1 \times 10^4$ CFU/µg. HGT mediated by *K. pneumoniae*-PRM OMVs occurred with a transformation efficiency of $7.8 \pm 0.9 \times 10^3$ CFU/µg. In both conditions, no plasmid acquisition occurred when recipient cells were incubated with free plasmid (Figure 4A–H). Therefore, HGT via OMVs derived from *K. pneumoniae*-pGR was 3.6 times more efficient than the *K. pneumoniae*-PRM OMVs transfer, with the same vesicular concentration (Figure 4I). Colony-PCR was used to confirm that resistant acquisition. PGR and PRM were determined by amplifying a region of the β-lactamase gene and the amplicon was visualized by agarose gel electrophoresis (Figure 5A,B). PCR analysis showed that all grown and selected colonies on LB-ampicillin plates contained pGR and PRM plasmids. Pre-transformation colonies of *K. pneumoniae* did not show amplification, demonstrating the absence of resistance. Amplification of the 16S ribosomal gene region was used as a housekeeping control.

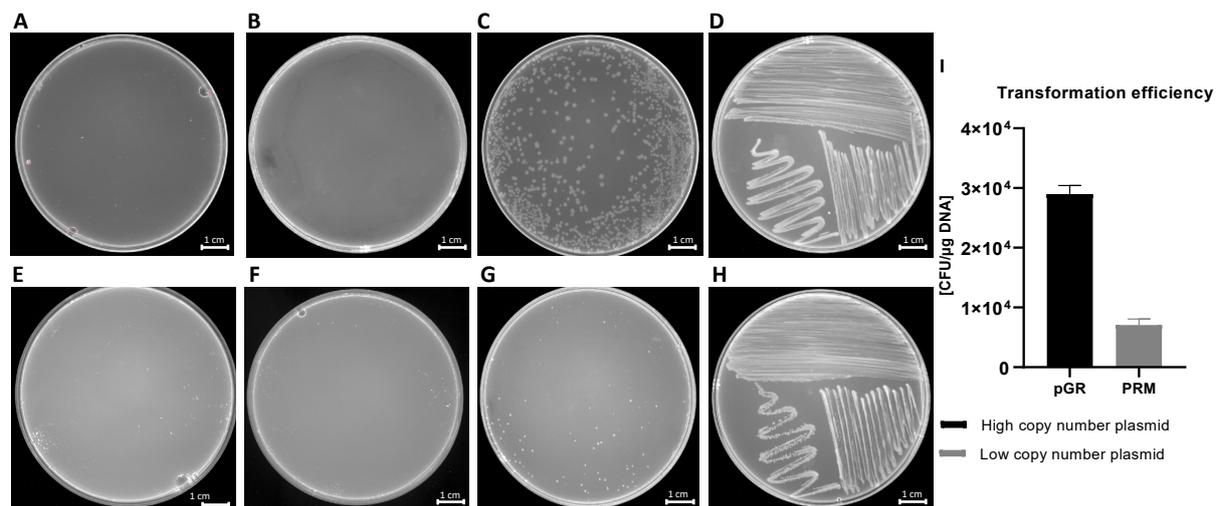

Figure 4. HGT via OMVs derived from *K. pneumoniae*-pGR. Untreated cells (**A**) and cells treated with free plasmid (**B**) did not record transformants. *K. pneumoniae* ATCC treated with 10 µg of OMVs (**C**) and bacteria control on LB-plates (**D**). HGT-OMVs from *K. pneumoniae*-PRM. Transformation in untreated (**E**) and treated with free plasmid (**F**) bacteria did not occur. *K. pneumoniae* ATCC incubated with 10 µg of OMVs (**G**) and bacteria control on LB-plates (**H**). Comparison of intra-species HGT efficiency via purified OMVs from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM (**I**).

2.4. OMVs Induce the Generalized Resistance Spread

The OMVs potential to transfer genetic material between different microbial species was evaluated. Five recipient bacterial species were selected based on taxonomic differences (Figure 6A). Cultures of *K. pneumoniae*, *E. coli*, *S. enterica*, *P. aeruginosa* and *B. cepacia* were treated with *K. pneumoniae*-pGR OMVs. After 24 h of incubation, recipient cells were plated on LB-ampicillin agar plates and counted to define the transformation efficiency. OMVs derived from *K. pneumoniae*-pGR transferred plasmid DNA with a transformation efficiency of $2.8 \pm 0.1 \times 10^4$, $1.7 \pm 0.2 \times 10^4$, $1.5 \pm 0.9 \times 10^4$, $1.6 \pm 0.1 \times 10^4$, and $1.8 \pm 0.8 \times 10^4$ CFU/µg for *K. pneumoniae*, *E. coli*, *S. enterica*, *P. aeruginosa* and *B. cepacia*, respectively (Figure 6B). Colonies of each recipient bacterial species were selected and subjected to PCR analysis to confirm the presence of the β-lactamase gene in the recipient species (Supplementary Figure S3A–D). Recipient cells incubated with free plasmid pGR and untreated cells did not acquire antibiotic resistance in any condition.
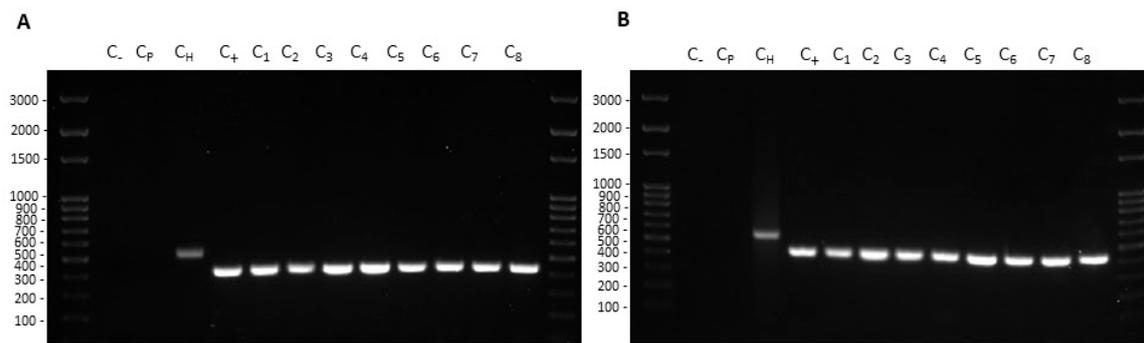

Figure 5. Colony-PCR from recipient cells treated with *K. pneumoniae*-pGR (**A**) and *K. pneumoniae*-PRM (**B**) OMVs. DNA gel showed PCR products with expected lengths: ß-lactamase product~424 bp (C_{1-8}), ribosomal 16S product~550 bp (C_H). Control water (C_-) and untreated bacteria (C_p) did not show amplification.

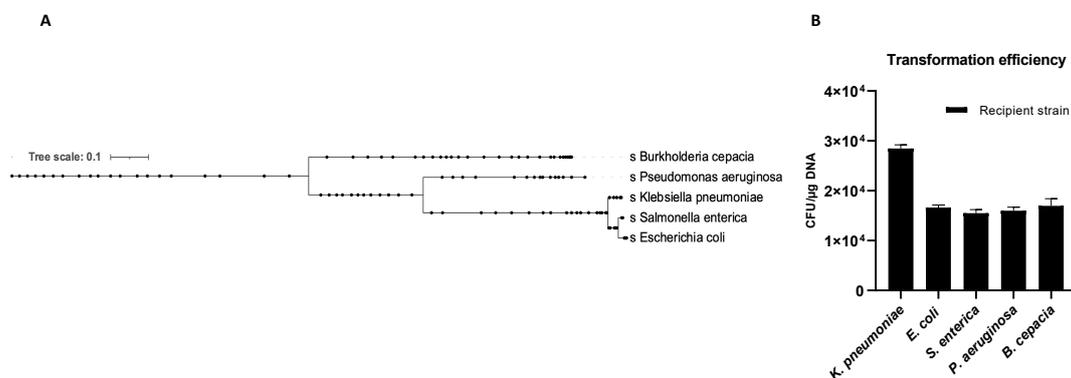

Figure 6. Phylogenetic relationship of the recipient species (**A**). *K. pneumoniae*-pGR OMVs inter-species transformation efficiency (**B**).

2.5. OMVs Stability over Time

OMV-HGT experiments continued to evaluate transformation efficiency over time, by storing OMVs derived from *K. pneumoniae*-pGR at $-20\ ^\circ$C for 30 days and at $+4\ ^\circ$C for 7 days. A gradual reduction in transformation efficiency was observed using OMVs treated with DNase and stored at $-20\ ^\circ$C and $+4\ ^\circ$C for increasing periods of time. The HGT experiment was conducted using *K. pneumoniae* ATCC as a recipient cell. The maximum number of transformants was obtained with OMVs used after 10 days of storage, showing an efficiency of $2.5 \pm 0.1 \times 10^4$ CFU/µg. After 20 days, a reduction in efficiency was verified, recording $7.7 \pm 0.9 \times 10^3$ CFU/µg. On the 30th day of storage, a drastic decrease of transformants had occurred, registering $9.1 \pm 0.12 \times 10^2$ CFU/µg. The OMVs stability at $+4\ ^\circ$C showed a slight reduction over time. The recorded transformation efficiency was $1.7 \pm 0.25 \times 10^4$ and $8.0 \pm 0.43 \times 10^3$ CFU/µg, after 3 and 7 days of storage, respectively (Figure 7).

2.6. Diagnostic Transformed Strains Characterization

The phenotypic effect correlated to the genotypic resistance detected by PCR analysis was evaluated through antibiotic susceptibility testing. Each bacterial strain, before and after treatment with OMVs derived from *K. pneumoniae*-pGR, was examined. Concerning the susceptibility to β-lactams, the inhibition diameters measured before OMVs treatment were 14.5 ± 0.3, 14 ± 0.01, 18.3 ± 0.07, 25 ± 0.5, and 20 ± 0.9 mm for *K. pneumoniae*, *E. coli*, *S. enterica*, *P. aeruginosa* and *B. cepacia*, respectively. Inhibition zones recorded were associated with susceptible strains, in accordance with EUCAST guidelines. After the OMV-HGT, no inhibition area was identified for β-lactam antibiotics, demonstrating the acquisition of resistance. The inhibition area measured for ciprofloxacin was ≥ 30 mm, before and after OMVs treatment, in each bacterial species (Figure 8). The ciprofloxacin

control was used to demonstrate that the acquired resistance was associated with the plasmid containing β-lactamase gene.

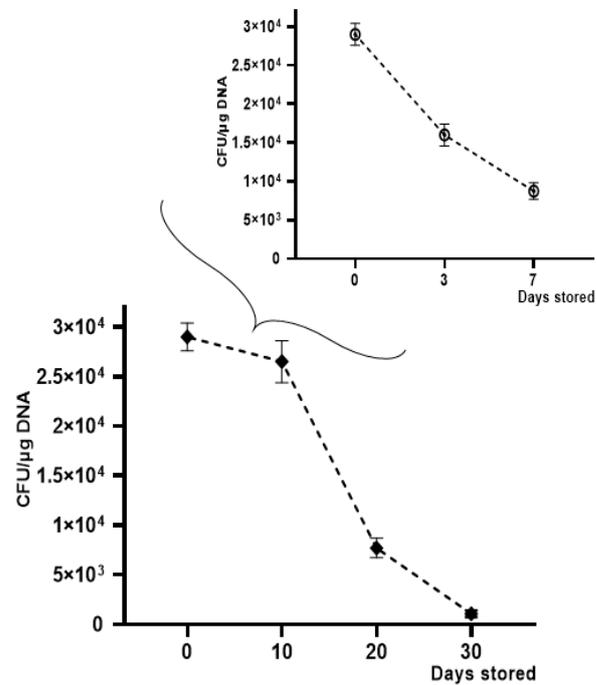

Figure 7. Transformation frequency of *K. pneumoniae*-pGR OMVs storage at −20 °C and +4 °C for 30 and 7 days, respectively.

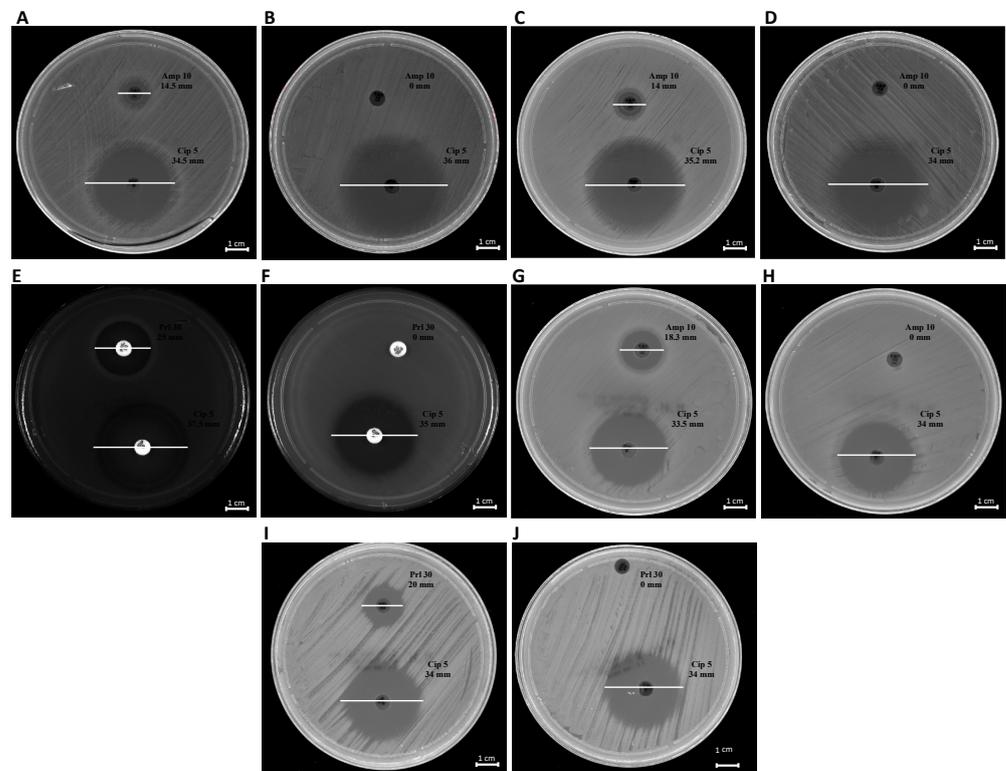

Figure 8. Antibiotic susceptibility of bacteria to ß-lactams. *K. pneumoniae* pre- and post-OMVs treatment (**A**,**B**); *E. coli* pre and post-OMVs treatment (**C**,**D**); *P. aeruginosa* pre- and post-OMVs treatment (**E**,**F**); *S. enterica* pre- and post-OMVs treatment (**G**,**H**); *B. cepacia* pre- and post-OMVs treatment (**I**,**J**).

3. Discussion

Horizontal gene transfer plays an important role in promoting bacterial evolution, adaptation to environmental changes and acquisition of new metabolic capabilities [3]. Genetic pool modifications as a consequence of genetic transfer were observed in bacterial communities with high frequency rates, demonstrating the importance of this phenomenon for bacterial survival [35]. Currently, transformation, transduction and conjugation are considered the three canonical HGT mechanisms, contributing significantly to genetic diversity [36]. However, novel genetic material exchange events are under consideration and may be added to those currently known. Nowadays, the HGT mechanism should include the OMVs secretion by Gram-negative bacteria [37]. Previous studies reported that OMVs incorporated DNA into the lumen and transported it to recipient cells [38]. Currently, no studies have assessed the ability of *K. pneumoniae* to exploit HGT via OMVs to spread antimicrobial resistance. However, multidrug-resistant *K. pneumoniae* is increasingly implicated in hospital-acquired infections causing mortality rates above 50% [39,40]. This bacterial species causes a wide variety of often untreatable diseases as a consequence of a relatively frequent acquisition of antibiotic resistance genes [41]. Improved understanding of *K. pneumoniae* mechanisms to resistance genes spread is needed to limit such a serious threat to global health. Therefore, the focus of the present research was the preliminary characterization of HGT mechanisms mediated by OMVs derived from *K. pneumoniae*. In detail, we demonstrated, for the first time, that OMVs derived from *K. pneumoniae* were able to incorporate genetic determinants of resistance during the biogenesis process. While protected within the vesicular lumen, antibiotic resistance genes were transferred to different bacterial species, through fusion of the vesicles with the outer membrane of the recipient species, therefore conferring a novel resistance to recipient cells.

Firstly, OMVs were isolated from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM, respectively. TEM and DLS analysis revealed that the vesicles featured a spherical morphology, in accordance with our previously published data, but with a reduced diameter compared with the OMVs collected from *K. pneumoniae* ATCC [14]. The different vesicular size could be attributed to the antibiotic presence during bacterial growth. Indeed, Fulsundar et al. showed that antibiotic and environmental stresses determined a significant effect on the OMVs production, size and DNA content [17]. These evidences confirm that OMVs release is a physiologically controlled process, dependent on environmental factors. The proteomic characterization of OMVs derived from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM identified more than 55 proteins, mainly from the outer membrane and the periplasmic space. Inner membrane and cytosolic proteins were also detected, demonstrating that, although the mechanism of inclusion is unclear, cytoplasmic components and portions of membrane were incorporated into OMVs during the biogenesis process. Finally, the presence of proteins capable of interacting with DNA could confirm the ability of OMVs to also incorporate genetic material. These results may suggest, in addition to the OMVs originating from outer membrane budding, the possible existence of another vesiculation pattern. Indeed, Cruez et al. showed in *S. vesiculosa* M7T, *N. gonorrhoeae*, *P. aeruginosa* PAO1 e, and *A. baumannii* AB41 the presence of vesicles containing a bilayer of membrane and highly electrodense cytoplasmic material. These vesicles were classified as outer-inner membrane vesicles (O-IMVs) [42]. The possible secretion of two vesicle types, OMVs and O-IMVs, could explain how DNA is incorporated in OMVs, since it is not properly clarified. Currently, three models have been proposed: (i) the DNA present in the extracellular environment was internalized according with a mechanism similar to bacterial transformation; (ii) DNA was transported through the inner membrane and the cell wall up to the periplasmic space, where it was included in the OMVs; (iii) the DNA inclusion in the vesicles occurred through the secretion of O-IMV, which incorporate cytoplasmic components and DNA. The third model is the most accredited and supported by experimental evidence [20]. Although the DNA inclusion mechanism is not known with absolute certainty, our findings demonstrated that OMVs secreted by *K. pneumoniae* were involved in HGT, allowing the spread of resistance genes in microbial communities.

Contextually, our manuscript demonstrated that *K. pneumoniae* transferred genetic material, incorporating DNA within the OMVs and protecting it from the extracellular exonucleases action. The DNA in the vesicular lumen was transferred to the recipient cell by determining the acquisition of resistance genes present in the plasmid. The recipient cell *K. pneumoniae*, after contact with OMVs, acquired and expressed resistance to ampicillin, proving the OMVs ability to promote intraspecies HGT. Plasmid transfer did not occur when cells were incubated with free plasmid, suggesting that vesicles could represent a physiological mechanism that exceeds environmental limits (exonuclease degradation, dilution of gene material, long-distance transfer, etc.) and associated with the donor/recipient cell (state of competence, high vesicle-OM affinity, correlation phylogenetics, etc.). Moreover, the transfer efficiency over time of the stored OMVs was evaluated. The transfer rates remained unchanged for up to 10 days. Thereafter, the number of transformants gradually decreased for up to 30 days. Similar trends were shown in the study conducted by Chatterjee et al. on OMVs derived from *A. baumannii*, confirming the long-lasting stability without cryopreservatives [27]. Subsequently, it was investigated whether plasmid identity affected incorporation and transfer rate. The transfer of two different plasmids via *K. pneumoniae*-OMVs was examined, showing that the plasmid type induced changes in packaging and transformation rate. The high copy number plasmid (pGR) was loaded and transferred with greater efficiency compared to the low copy number plasmid (PRM). Our results were in line with a study conducted by Tran and Boedicker, in which the low copy number plasmid (pZS2501) had a low loading capacity (0.49×10^3 copies per pg of OMVs), while the high copy number plasmids (pLC291 and pUC19) showed a high loading potential (2.58×10^3 and 482.7×10^3 copies per pg of OMVs) [16]. Therefore, the plasmid cargo in the OMVs was strictly dependent on the copy number; the higher the PCN, the greater the plasmid amount in the OMVs and consequently the transformation efficiency. OMVs-mediated transfer exceeds the limits observed in other HGT mechanisms [43]. Chatterjee et al. have already reported the ability of *A. baumannii*-OMVs to allow interspecies gene transfer [27]. For this reason, interspecies gene exchange was observed via *K. pneumoniae*-OMVs, using four different recipient species: *E. coli*, *S. enterica*, *P. aeruginosa* and *B. cepacia*. The generalized transfer to the different bacterial genera highlighted the HGT-OMVs efficiency, which verified independently of the phylogenetic correlation between the donor and recipient cell. Our experimental evidence showed that OMVs contributed to genetic exchange in microbial communities even among distantly related bacteria, without specific exchange mechanisms. Future studies will examine the possibility of OMVs to exchange DNA between different Gram-positive species.

In summary, the present study demonstrates, for the first time, the resistance gene to β-lactams spreads through OMVs secreted by *K. pneumoniae*. This innovative HGT mechanism allows for intra-species or inter-species diffusion, persistent over time and apparently not associated with specific limitations. Our study reveals a novel gene transfer mechanism of resistance genes that may contribute to the spread of antibiotic resistance between different bacterial species. Understanding the distribution of resistance determinants in several bacterial populations and clarifying the factors that promote their spread could be useful for identifying new pharmacological targets to limit the spread of antibiotic resistance.

4. Materials and Methods

4.1. Bacterial Strains, Plasmids and Growing Conditions

The strains used in this study were obtained from the American Type Culture Collection (ATCC) (Manassan, VA, USA). *K. pneumoniae* ATCC 10031 was used for the OMVs purification. *K. pneumoniae* was transformed using the calcium chloride method with pGR (*K. pneumoniae*-pGR) (Addgene, Watertown, MA, USA) and PRM-GFP (*K. pneumoniae*-PRM) (Addgene, Watertown, MA, USA), respectively [44,45]. The first one was a high copy number plasmid (500~600 copies) containing genes for green fluorescent protein (GFP) and β-lactamase which conferred resistance to ampicillin. PRM was a plasmid containing

the same genes and differed in copy number (10~12 copies). After transformation, *K. pneumoniae*-pGR and *K. pneumoniae*-PRM were cultured on Luria-Bertani agar (LB) (Sigma-Aldrich, St. Louis, MO, USA) containing 100 µg mL^{-1} of ampicillin (Sigma-Aldrich, St. Louis, MO, USA). *E. coli* ATCC 25922, *S. enterica* ATCC 14028, *P. aeruginosa* ATCC 13388 and *Burkholderia cepacia* ATCC 25416 were used as recipient strains for the HGT mediated by OMVs. All bacterial strains were cultured in LB (Sigma-Aldrich, St. Louis, MO, USA) medium at 37 °C under orbital shaking at 180 rpm.

4.2. OMVs Purification

OMVs were isolated from liquid cultures of *K. pneumoniae*-pGR and *K. pneumoniae*-PRM-GFP as previously described with modifications [46]. First, 10 mL of overnight (O/N) bacterial culture was inoculated in 600 mL of LB containing 100 µg mL^{-1} ampicillin. The bacterial inoculum was cultured at 37 °C under orbital shaking (180 rpm) for 8–12 h, up to the OD$_{600}$ nm value of 1. The cultures were centrifuged at 4000× *g* at 4 °C for 20 min, to remove bacterial cells. Supernatants were decanted and filtered using vacuum Stericup™ 0.45 µm and 0.22 µm pore size polyethersulfone (PES) top filter (Millipore, Burlington, MA, USA), to deflect remaining bacteria and cell debris. Vesicles were collected from cell-free supernatant culture by ultracentrifugation at 100,000× *g* (centrifuge Optima XPN-100 Beckman Coulter and rotor SW28) at 4 °C for 1.5 h. Pellets were washed in sterile phosphate buffered saline 1X (PBS) by ultracentrifugation (100,000× *g* at 4 °C for 1.5 h). Vesicular pellets were suspended in 250 µL of PBS 1X and OMVs sterility was checked by inoculating 10 µL of vesicles on LB-agar plates. OMV samples were treated with DNase (Applied Biological Materials (abm), Richmond, BC, Canada) according to the manufacturer's protocol and stored at −20 °C until use.

4.3. Transmission Electron Microscopy (TEM)

Purified OMVs were visualized by TEM, using negative staining. Five microliters of sample were adsorbed on carbon-coated copper/palladium grids for 30 min. A drop of sterile deionized water was used to wash the grids and a negative staining was realized by addition of 5 µL of 1% (*w/v*) uranyl acetate. TEM images were acquired using an EM 208 S transmission electron microscope (Philips, Amsterdam, The Netherlands).

4.4. OMVs Size Characterization by Dynamic Light Scattering (DLS)

Vesicle diameter size (Z-ave) and PDI analysis were performed using Zetasizer Nano-ZS (Malvern Instruments, Worcestershire, UK). For DLS, 40 µL of OMVs aliquot were mixed gently and transferred to sterile cuvettes. All measurements were conducted at 25 °C and three independent experiments for each purification were performed. DLS data were processed using Zetasizer software (V 7.11) provided by Malvern Panalytical (Malvern, UK).

4.5. OMVs Protein Profile by Tandem Mass Spectrometry (MS/MS)

For protein profile, OMVs were incubated with 1% Triton X-100 for 1 h at 4 °C. Lysed vesicles were centrifuged at 14,000× *g* at 4 °C for 30 min and the supernatant was examined for protein amount by Bradford assay (HIMEDIA, Maharashtra, India). The protein extract was subjected to 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). The gel was stained with Coomassie Brilliant blue G250 (Sigma-Aldrich, St. Louis, MO, USA) and different bands were cut to perform MS and MS/MS analysis, as previously described [14]. Briefly, protein bands were extracted from the gel and digested with trypsin. NanoUPLC-hr MS/MS analysis of the resulting peptide mixtures were performed on a Q-Exactive orbitrap mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA), coupled with a nanoUltimate300 UHPLC system (Thermo Fisher Scientific, USA). For protein identification, mass spectra were subjected to analysis by Mascot software (v2.5, Matrix Science, Boston, MA, USA), using the non-database redundant UniprotKB/Swiss-Prot (version 2020_03). The identified proteins were analyzed

by subcellular localization, biological processes and molecular functions using Uniprot software (https://www.uniprot.org/ (accessed on 14 March 2021)).

4.6. Intra-Vesicular DNA Analysis

Plasmid concentration in OMVs was determined by Real-time PCR (qPCR) using BrightGreen qPCR MasterMix Kits (abm, San Francisco, CA, USA), according to the manufacturer's instructions. For DNA extraction, vesicles were lysed by boiling at 100 °C for 10 min. Two microliters of OMVs were added to 0.2 µM of primer, 1X mastermix in a final reaction volume of 20 µL. Primers used for qPCR were: β-lactamase Fw 5′-AACTTTATCCGCCTCCATCC-3′, and β-lactamase Rev 3′-GCTATGTGGCGCGGTATTAT-5′. The amplification was performed in CFX96 Touch Real-Time PCR Detection System (Bio-Rad, California, USA), using the following amplification program: denaturation at 95 °C for 15 s, annealing at 60 °C for 20 s and extension at 72 °C for 15 s (40 cycles). The standard curves were constructed using purified plasmids from *K. pneumoniae*-pGR and *K. pneumoniae*-PRM, respectively. Plasmid concentration in OMVs was converted in plasmid copy number (PCN), according to the formula:

$$\text{PCN} = \frac{ng\ DNA \times 6.022 \times 10^{23}}{length \times 1 \times 10^9 \times 650}$$

http://cels.uri.edu/gsc/cndna.html (accessed on 29 January 2004) Subsequently, plasmid loading was estimated based on OMVs protein concentrations.

4.7. OMVs-Mediated Gene Transfer

For gene transfer experiments through OMVs, the recipient strains *K. pneumoniae* ATCC, *E. coli* ATCC, *P. aeruginosa* ATCC, *B. cepacia* ATCC and *S. enterica* ATCC were inoculated in LB-broth up to OD_{600} nm value of 0.4. Cells were diluted in cold LB at final concentration of 10^7 CFU/mL. Bacterial suspensions (60 µL) were incubated with 10 µg of OMVs statically for 4 h at 37 °C and, subsequently, for 4 h under orbital shaking (180 rpm) at 37 °C. Fresh LB-medium was added to each bacterial suspension and then incubated O/N under orbital shaking (180 rpm) at 37 °C. To further confirm that the plasmid transfer was mediated by OMVs, two separate experiments were performed with: (i) free plasmid and (ii) untreated cells. The following day, a 100 µL aliquot of bacteria was plated on LB-agar supplemented with 100 µg mL^{-1} ampicillin and incubated O/N at 37 °C. The bacterial colonies (C_{1-8}) were counted to define the transformation efficiency, according to the formula:

$$\text{Transformation efficiency [CFU/µg]} = \frac{Number\ of\ colonies \times Diluition\ factor}{DNA\ quantity}$$

The same transformation experiments were performed using OMVs stored at −20 °C for 10, 20 and 30 days and OMVs stored at +4 °C for 3 and 7 days.

4.8. Polymerase Chain Reaction (PCR) Screening

After OMVs gene transfer, bacterial colonies grown on LB-agar supplemented with 100 µg mL^{-1} ampicillin were selected and subjected to molecular investigation for the presence of the plasmid by colony-PCR. Each bacterial colony was lysed by heat-shock and then centrifuged at 16,000× *g* at 4 °C for 10 min. The supernatant was transferred to a new Eppendorf and the DNA concentration was examined by NanoDrop 1000 spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA). PCR was performed in a total volume of 50 µL containing 1 µM each primer, 1X Taq Master Mix (abm, San Francisco, CA, USA) and 100 ng of DNA. The primers used to amplify the 424 bp region of β-lactamase gene were: Fw 5′-AACTTTATCCGCCTCCATCC-3′, and Rev 3′-GCTATGTGGCGCGGTATTAT-5′. The amplification was conducted in Thermal Cycler UNO96 (VWR International, Pennsylvania, USA) according to the following program: initial denaturation at 94 °C for 3 min,

35 cycles of amplification in which each cycle was denatured at 94 °C for 30 s, annealed at 57.3 °C for 30 s and extended at 72 °C 1 min; the final extension at 72 °C for 5 min. As a housekeeping gene control, 16S rRNA gene was amplified, using the primers: Fw 5′-GGTAGAGTTTGATCCTGGCTCAG-3′, and Rev 3′-ATTACCGCGGCTGCTGG-5′. The used program was: initial denaturation at 94 °C for 1 min, 30 cycles of amplification in which each cycle was denatured at 94 °C for 1 min, annealed at 58 °C for 1 min and extended at 72 °C for 1.5 min; the final extension at 72 °C for 10 min. To visualize the amplification product, 1% agarose gel electrophoresis was performed.

4.9. Antibiotic Susceptibility Test

The disk diffusion assay was performed according to the National Committee on Clinical Laboratory Standards (NCCLS) [47,48]. Fresh colonies, before and after OMVs treatment, were inoculated in physiological solutions to 0.5 McFarland turbidity. With a cotton swab dipped in the bacterial inoculum, the solution was homogeneously plated into Mueller-Hinton (MH) agar plates. Disks of ampicillin (10 μg) (Thermo Fisher Scientific, Waltham, MA, USA), piperacillin (30 μg) (Thermo Fisher Scientific, Waltham, MA, USA) and ciprofloxacin (5 μg) (Thermo Fisher Scientific, Waltham, MA, USA) were placed on the plates and were incubated at 37 °C O/N. The antibiotic susceptibility was examined by measuring the zone of inhibition diameter, according to the European Committee on Antimicrobial Susceptibility Testing (EUCAST) guidelines.
