Abstract

Background: Lithium is widely used to treat bipolar disorders and displays mood stabilizing properties. In addition, lithium relieves painful cluster headaches and has a strong analgesic effect in neuropathic pain rat models.

Objectives: To investigate the analgesic effect of lithium on the cuff model of neuropathic pain.

Methods: We used behavioral and pharmacological approaches to study the analgesic effect of a single injection of lithium in wild-type and mu opioid receptor (MOR) null cuffed neuropathic mice. Mass spectrometry and enzyme-linked immunosorbent assay allowed to measure the levels of endogenous MOR agonist beta-endorphin as well as monoamines in brain and plasma samples 4 h after lithium administration.

Results: A single injection of lithium chloride (100 mg/kg, ip) alleviated mechanical allodynia for 24 h, and this effect was absent in MOR null neuropathic mice. Biochemical analyses highlight a significant increase in beta-endorphin levels by 30% in the brain of lithium-treated mice compared to controls. No variation of beta-endorphin was detected in the blood.

Conclusions: Together, our results provide evidence that lithium induces a long-lasting analgesia in neuropathic mice presumably through elevated brain levels of beta-endorphin and the activation of MORs.

Background

Lithium is a metallic ion displaying chaotropic and denaturing properties.[1] This metal is described to treat bipolar disorders,[2] to be able to reduce painful cluster headache[3] and to decrease inflammation.[4] Several research groups reported functional interactions between lithium and the opioid system. In particular, lithium affects morphine-induced analgesia,[5,6] and reduces morphine tolerance and dependence.[7,8] Lithium attenuates thermal hyperalgesia and mechanical allodynia in different models of neuropathic pain in rats via a naloxone-sensitive mechanism, suggesting that lithium action is opioid receptor dependent.[9,10] In addition, lithium prevents paclitaxel-induced peripheral neuropathy,[11]

increases survival by allowing the use of higher doses of paclitaxel, and prevents paclitaxel-induced cardiac abnormalities.

The present study reveals that a single injection of lithium alleviates neuropathic pain symptoms in a mouse model of sciatic nerve chronic constriction and demonstrates for the first time mu opioid receptor (MOR) involvement in lithium analgesia. In this context, the potential variations of endogenous opioid as well as monoamine levels have been studied after lithium injection.

Methods

Animals

Experiments were performed with 45-day-old adult male C57BL/6J mice (25 $\pm$ 4 g; Charles River, L'Arbresle, France). MOR null mice were a generous gift from Professor B. Kieffer (IGBMC, Illkirch-Graffenstaden, France). Animals were given free access to food and water, with a 12 h light-dark cycle at a temperature of 22°C $\pm$ 2°C. All procedures were performed in accordance with European directives (2010/63/EU) and were approved by the regional ethics committee and the French Ministry of Agriculture (license No. 00456.02 to Y.G.). The right sciatic nerve was cuffed with a section of polyethylene tubing (cuff group) as previously described.[12] Briefly, surgeries were done under aseptic conditions and ketamine/xylazine was used for anesthesia (ketamine: 17 mg/mL, i.p., xylazine: 2.5 mg/mL, i.p., 4 mL/kg; Centravet, Taden, France). After performing a 1.5 cm skin incision of the right hind thigh, a 2 mm long polyethylene tubing was placed on the common branch of the right sciatic nerve (internal diameter = 0.38 mm, external diameter = 1.09 mm; PE-20, Harvard Apparatus, Les Ulis, France) and sutures were used to close the skin.[12] Sham-operated mice underwent the same surgical procedure as cuffed animals without implantation of the cuff.

Response to mechanical stimuli

The mechanical threshold for hind paw withdrawal was determined using Von Frey hairs as previously described.[12] Intraperitoneal injections of a solution of 100 mg/kg of lithium chloride (corresponding to 16.4 mg/ml of lithium; Sigma-Aldrich, St. Louis, USA) diluted in NaCl 0.9% (w/v; saline), naloxone (Sigma-Aldrich) diluted in saline or an equivalent volume of saline were performed at 10 am. Injections of naloxone[13] (0.1 mg/kg, s.c.) were performed 4 h after the injections of lithium (corresponding to the peak of analgesia observed for neuropathic mice). Hind paw withdrawal was determined 15 min later.

Response to thermal stimuli

Mice were placed during 15 min in clear Plexiglas boxes (7 cm × 9 cm× 7 cm) on a glass surface.[14] The infrared beam of the radiant heat source (7370 Plantar Test, Ugo Basile, Comerio, Italy) was applied to the plantar surface of each hind paw. The cut-off to prevent damage to the skin was set at 15 s. The paw withdrawal latency was tested 3 times 4 h after lithium injection and was averaged for each hind paw.

Sample preparation

Plasma was prepared from blood recovered in tubes containing 50 µl of 2% EDTA (w/v) and protease inhibitors (cOmplete Mini EDTA-free, Roche, Basel, Switzerland).

Each brain was homogenized in 2 ml of 0.5 µM ascorbic acid containing protease inhibitors and sonicated for 10 s at 90 W and centrifuged (20,000 g, 15 min, 4°C). Supernatant was recovered and protein content was determined using the Protein Assay kit (Bio-Rad, Marnes-la-Coquette, France).

Monoamines and catecholamines derivatization

The presence of L-DOPA, dopamine, adrenaline, noradrenaline, serotonin, and adenosine was studied. Twenty microliters of tissue extracts or plasma were derived with the AccQ-Tag Ultra Derivatization kit (Waters, Guyancourt, France). Twenty microliters of the sample were added to 30 µl of borate buffer (provided within the kit) and 10 µl of internal standards ([^{2}H$_3$]-L-DOPA, [^{2}H$_4$]-dopamine, [^{2}H$_6$]-adrenaline, [^{13}C$_6$]-noradrenaline, [^{2}H$_4$]-serotonin, [^{13}C$_5$]-adenosine; Sigma Aldrich and Alsachim, Illkirch, France). Derivatization was performed by addition of 10 µl of AccQtag Ultra reagent (10 min, 55°C under agitation). Ten microliters of this solution were analyzed using a LC-MS/MS approach.

Beta-endorphin enzyme-linked immunosorbent assay

Beta-endorphin concentrations in the brain and plasma were quantified using a direct enzyme-linked immunosorbent assay (ELISA) (M0184 ELISA, Clinisciences-Elabscience, Nanterre, France) according to the manufacturer's instruction. Samples (50 µl) were analyzed in duplicate. All samples with a duplicate CV > 5% were retested to obtain a CV below or equal to 5%. Detection range was 15.63-1000 pg/ml and sensitivity was 9.38 pg/ml of beta-endorphin.

LC-MS/MS instrumentation and analytical conditions

Analyses were performed with a Dionex Ultimate, 3000 HPLC system (Thermo Scientific, San Jose, USA) coupled with a triple quadrupole Endura. The system was

controlled by Xcalibur v2.0 software. Samples were loaded onto an Accucore RP-MS column (100 × 2.1 mm, 2 μm, Thermo Electron) heated at 50°C. Buffer A was H$_2$O 99.9%/formic acid 0.1% (v/v), whereas buffer B was ACN 99.9%/formic acid 0.1% (v/v). Gradient used is detailed in Table 1.

Electrospray ionization was achieved in the positive mode with the spray voltage set at 3750 V. Nitrogen was used as the nebulizer gas and the ionization source was heated to 250°C. Desolvation (nitrogen) sheath gas was set to 45 Arb and Aux gas was set to 15 Arb. Ion transfer tube was heated at 350°C. Q1 and Q2 resolutions were set at 0.7 full width at half maximum (FWHM), whereas collision gas (CID, argon) was set to 2 mTorr. Identification of the compounds was based on precursor ion, selective fragment ions, and retention times. Selection of the monitored transitions and optimization of collision energy and radio frequency (RF) lens parameters were manually determined (see Table 1 for details). Qualification and quantification were performed in multiple reaction monitoring (MRM) mode using Quan Browser software (Thermo Scientific). Limits of detection and of quantification for each compound are indicated in Table 2. All amounts of opiates present in samples fit within the standard curve limits. Precision values were <1% for same-day measurements and <5% for inter-day measurements.

Statistics

Statistical analysis was performed using GraphPad Prism 6 Software. Results were presented as mean values ± standard error of the mean. Groups were compared using analysis of variance tests with Bonferroni correction.

Results

Effect of lithium on the mechanical nociceptive threshold in the cuff neuropathic pain model

Cuff and Sham mice were tested for mechanical pain threshold using the Von Frey filaments test. The cuff group showed a significant mechanical allodynia compared to the sham group (Figure 1(a)). Lithium injection performed six days after surgery did not affect the

Note: LOD was defined as the lowest detectable amount of analyte with a signal-to-noise (S/N) ratio >3. LOQ was defined as the lowest detectable amount of analyte with a signal-to-noise (S/N) ratio >10. Data are presented as the mean ± SEM of five measurements.
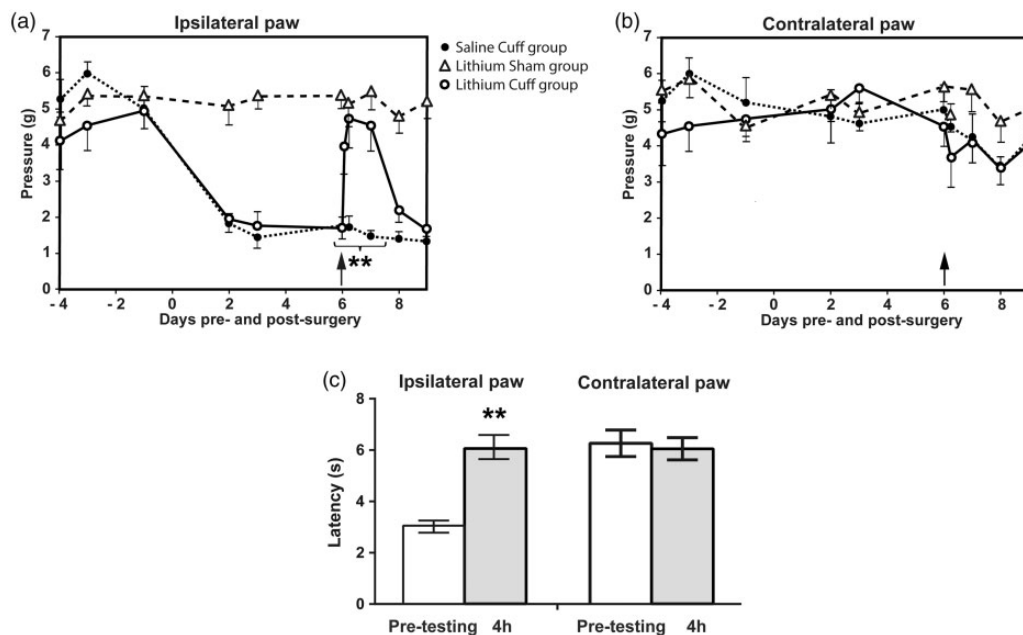

Figure 1. Antinociceptive effect of lithium chloride (100 mg/kg, i.p., day 6) on sham and cuffed mice. Effect of lithium administration on (a) ipsilateral paw mechanical allodynia and (b) contralateral paw (n = 6; two-way ANOVA test with a Bonferroni correction; $**p < 0.01$). (c) Effect of lithium 4 h after administration on thermal hyperalgesia (6 days after the surgery; Hargreaves test; n = 6; Mann–Whitney U test; $**p < 0.01$). Values are means ± SEM.

mechanical pain threshold of the sham group. Conversely, in the neuropathic cuff group, lithium normalized the ipsilateral mechanical pain threshold to sham group values. This analgesic effect of a single injection lasted for about 24 h (Figure 1(a)). The contralateral paw mechanical pain threshold was unaffected (Figure 1(b)), and no statistical difference before and after lithium injection was observed. Additional experiments were designed to determine the effect of lithium 4 h after administration on thermal hyperalgesia (6 days after the surgery). The Hargreaves test (Figure 1(c)) showed a significant relief of thermal hyperalgesia for the ipsilateral paw compared to the pretest condition (before lithium administration; n = 6; Mann–Whitney U test; p < 0.01). Heat-nociceptive threshold of the contralateral paw was not affected by lithium.

Effect of naloxone on lithium-induced analgesia

In order to determine if this analgesic effect involves the endogenous opioid system, naloxone (0.1 mg/kg, s.c.), a non-specific opioid receptor antagonist, was administered 4 h after lithium injections (corresponding to the-peak of analgesia observed for neuropathic mice; Figure 1(a)). Naloxone alone did not modify the mechanical threshold but significantly decreased the analgesic effect of lithium (Figure 2(a)). The contralateral paw mechanical pain threshold was not affected.
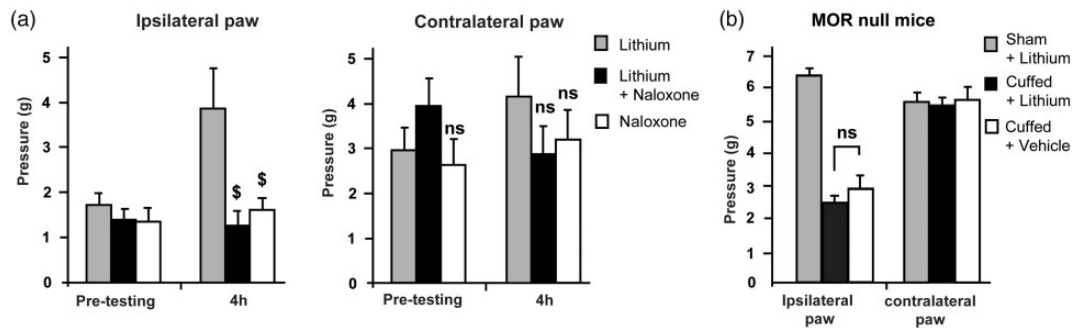

Effect of lithium on neuropathic MOR-null mice

To assess whether MORs were necessary for lithium analgesia, sham and cuff MOR null mice were treated with a single injection of lithium. Lithium-induced analgesia was never observed in MOR-null mice (Figure 2(b)) as illustrated by the stability of the mean mechanical threshold observed in lithium and vehicle-treated cuffed mice. No effect was observed on the contralateral paw mechanical pain threshold.

### Effect of lithium on the level of endogenous mediators

While MORs have been long known to promote analgesia, opioid ligands such as beta-endorphin as well as non-opioid neurotransmitters may be produced locally or after recruitment of classical pain controls acting in central nervous system (CNS) circuits or at the periphery. Plasma and brains of saline and lithium-treated neuropathic animals were analyzed using biochemical approaches aimed at measuring levels of noradrenaline, adenosine, serotonin, and beta-endorphin.

In the plasma, no differences between saline- and lithium-treated cuff groups were found (Figure 3). Adrenaline, dopamine, and L-DOPA were below detection levels. Values obtained for beta-endorphin, serotonin, noradrenaline, and adenosine were in agreement with values published in the literature.[15–18]

In the brain, adrenaline, noradrenaline, dopamine, L-DOPA, adenosine, and serotonin levels were not

Figure 2. Mu opioid receptor-dependent analgesic effect of lithium chloride on neuropathic mice. (a) Effect of naloxone (0.1 mg/kg, s.c.) on lithium-induced analgesia (100 mg/kg, i.p.; n = 6 per group; two-way ANOVA test with a Bonferroni correction; $^{\$}p < 0.01$). (b) Effect of lithium chloride on MOR null neuropathic mice (n = 6 per group, ANOVA test; n = 6. ns: non-significant). Values are means ± SEM. Pretesting group corresponds to mechanical threshold before lithium and/or naloxone injections. The 4-h group corresponds to mechanical threshold observed 4 h after lithium and/or naloxone injections. MOR: mu opioid receptor.
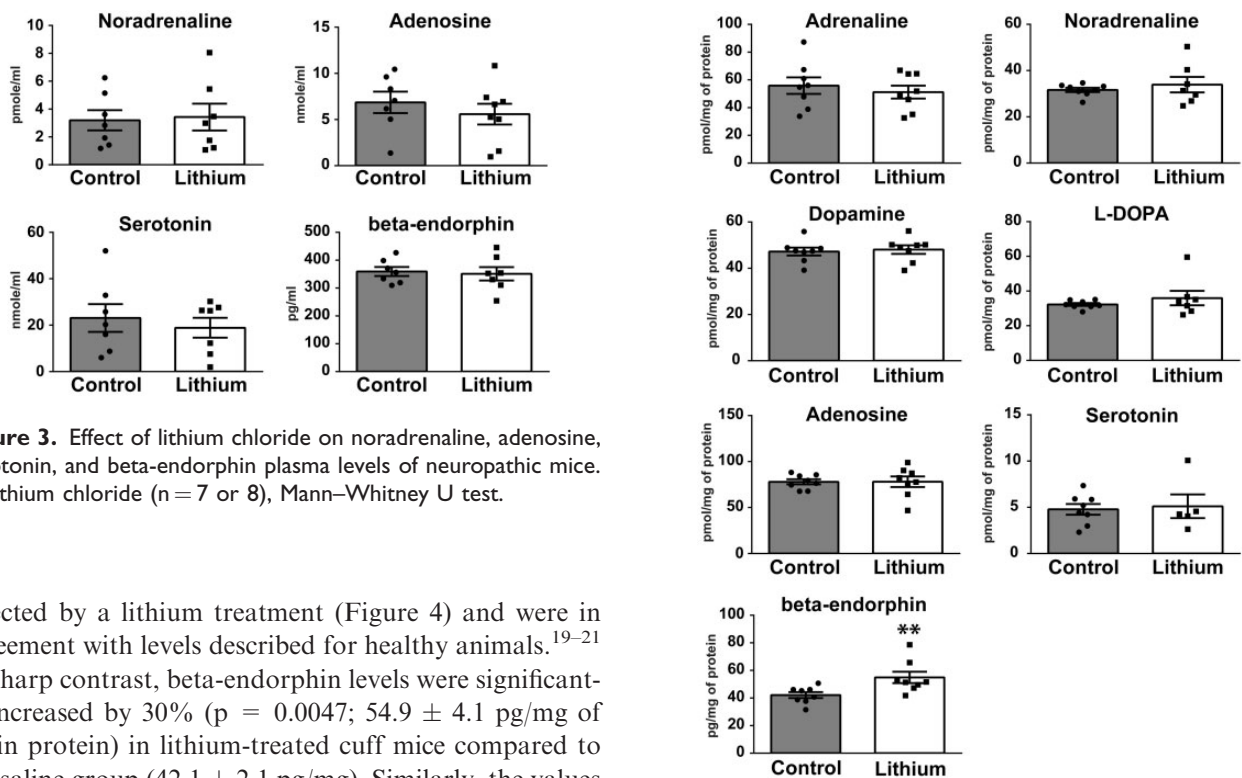

Figure 3. Effect of lithium chloride on noradrenaline, adenosine, serotonin, and beta-endorphin plasma levels of neuropathic mice. Li: lithium chloride (n = 7 or 8), Mann–Whitney U test.

Figure 4. Effect of lithium chloride on adrenaline, noradrenaline, dopamine, L-DOPA, adenosine, serotonin, and beta-endorphin brain levels of cuffed mice. Li: Lithium chloride; n = 8, 7, or 6 (please see graphs). Mann–Whitney U test. *$p < 0.05$; **$p < 0.01$. Values are means ± SEM.

affected by a lithium treatment (Figure 4) and were in agreement with levels described for healthy animals.[19–21] In sharp contrast, beta-endorphin levels were significantly increased by 30% (p = 0.0047; 54.9 ± 4.1 pg/mg of brain protein) in lithium-treated cuff mice compared to the saline group (42.1 ± 2.1 pg/mg). Similarly, the values of beta-endorphin brain levels (low pg/mg physiological range) are consistent with previous studies.[22]

Discussion

In addition to the physiological processing of acute pain by the nociceptive system, inflammatory and neuropathic insults may sometimes result in chronic pain that persists long after recovery from the initial lesions.[23] In such pathological states, pain no longer plays its physiological warning role. Most therapeutic approaches aimed at alleviating chronic pain symptoms have beneficial effects but suffer from adverse side effects.[24,25] This is the case for morphine and related opiates that are widely prescribed to chronic pain patients and may lead to the development of tolerance, opioid-induced hyperalgesia, and addiction.[26,27] Therefore, alternative therapeutic strategies are needed.

Studies examining the role of lithium on pain responses are unfortunately contradictory so far. On one side, lithium seems to induce hyperalgesia and decrease morphine-induced analgesia.[5,28,29] In addition, lithium overdose can, in a few cases, cause peripheral neuropathy or myopathy in patients.[30] In mice and rats, it has been hypothesized that lithium induces a biphasic effect on morphine-induced analgesia that is dependent on lithium concentration and on the pain test used.[6,31,32] On the other hand, several groups did not observe any direct effect of lithium on pain perception using a mouse model.[33]

Interestingly, lithium was shown to relieve cluster headache, which causes pain episodes of extreme intensity. Lithium also reduced the associated autonomic symptoms in humans.[34] Moreover, acute and chronic administration of lithium induce a direct analgesia in neuropathic pain states,[9,10,35] and potentiate morphine analgesia in mouse and rat models.[33,36] Lithium treatments also reversed thermal hyperalgesia as well as the mechanical and cold allodynia induced by a partial sciatic nerve ligation in rats in a naloxone-sensitive manner.[9,10] Furthermore, lithium has been shown to prevent paclitaxel-induced peripheral neuropathy in mice.[11] In humans, a clinical trial performed with lithium medication had a favorable effect on sciatic nerve injury neuropathic pain.[37] Moreover, lithium was able to relieve tricyclic antidepressants-refractory fibromyalgia.[38] Our present data confirm the long-lasting analgesic effect of acute lithium administration on a well-characterized mouse neuropathic model.[12] In addition, we show that MORs are necessary for lithium-induced analgesia, as no analgesic effect was observed in MOR-null mice.

Lithium acts on numerous targets that have been recently reviewed.[39,40] Different mechanisms of action have been proposed and include a possible substitution of Na^+ by Li^+ impacting homeostasis of electrolyte balance and therefore neuronal firing, or a modulation of the membrane transport of different ions and neurotransmitter precursors.[41] In rats, lithium-aversive effects (place-preference conditioning procedure) were abolished by naloxone, suggesting a beta-endorphin-dependent mechanism.[42] In addition to being a modulator of NO production in the brain, lithium inhibits Gi and Gs proteins leading to an inhibition of adenylate and guanylate cyclases and of different protein kinases.[43] Moreover, lithium affects GSK-3β (glycogen synthase kinase 3)[44] acting on both Akt (protein kinase B) and Wingless-related integration site (Wnt) signaling.[45] This compound is also able to inhibit inositol monophosphatase and inositol polyphosphate-1-phosphatase,[46,47] influencing inositol-dependent regulatory processes. It also reduces cyclic AMP-responsive element-binding protein (CREB) phosphorylation and decreases CREB-dependent gene expression.[48] Lithium's anti-inflammatory properties lead to a downregulation of both proinflammatory cytokines and TNF-alpha interleukin and intracellular mechanisms including GSK-3β.[4] Finally, lithium has also been shown to regulate the biosynthesis of different neurotransmitters and/or associated receptors (e.g., modulation of serotonin and glutamate synthesis and secretion).[42,49–52]

Our results indicate that acute lithium treatment has a strong anti-allodynic effect as well as a stimulatory effect (+30%) on the production of brain beta-endorphin, a MOR agonist displaying strong analgesic properties. In good agreement with our data, it has been described that stress-induced analgesia is absent in mice lacking beta-endorphin[53] and that ultraviolet light induces both analgesia and addiction through a 35% increase of plasma beta-endorphin levels.[15] More recently, photobiomodulation therapy performed on the chronic constriction injury mouse model correlated the level of pain relief to an increase of beta-endorphin levels.[54] However, this effect is still unclear since previous studies reported that in vivo chronic treatment with lithium did not modify beta-endorphin levels in different rat brain structures,[55] whereas in vitro and ex vivo experiments demonstrated that an acute stimulation with lithium increases the release of hypothalamic beta-endorphin.[56] As a 35% blood beta-endorphin increase induces a strong elevation of mechanical and thermal thresholds,[15] the 30% increase in beta-endorphin brain content we observed after lithium injection should likely be sufficient to induce robust analgesia.

Plasma levels of beta-endorphin are tightly linked to secretions from the pituitary and adrenal gland, whereas brain and cerebrospinal fluid levels are mainly dependent on the arcuate nucleus of the hypothalamus and of the brainstem nucleus tractus solitaris. In addition, beta-endorphin displays a short half-life in rodents' blood (2 to 10 min)[57,58] while in the CNS, degradation of beta-endorphin is described to be extremely long.[59,58]

Therefore, the beta-endorphin elevation observed in the brain 4 h after a lithium injection is likely due to an upregulation of beta-endorphin production from the arcuate nucleus and the nucleus tractus solitaris associated with a longer brain half-life. While the cuff is a model of peripheral neuropathy, CNS beta-endorphin secretion can normalize the ipsilateral paw threshold by acting on supraspinal (e.g., periaqueductal gray, rostral ventromedial medulla) or spinal nociceptors.

Together with other studies showing the analgesic effect of acute lithium treatment on chronic pain, our results suggest that lithium analgesia involves the upregulation of beta-endorphin synthesis in the CNS. This would explain, at least in part, the MOR-dependent nature of the analgesic properties of lithium.
