Transcriptomic Analyses Predict Enhanced Metabolic Activity and Therapeutic Potential of mTOR Inhibitors in Acne-Prone Skin

Mackenzie L. Sennett^{[1](#page-0-0)}, George W. Agak^{[2](#page-0-1)}, Diane M. Thiboutot¹ and Amanda M. Nelson¹

Current acne therapies center on preventing new lesions in patients with acne. These therapies were historically found to be beneficial yet were chosen without knowledge of the specific changes in the skin that favor lesion development. A major challenge in developing new treatments is the incomplete understanding of nonlesional (NL), acne-prone skin's molecular characteristics. To address this, we compared RNA-sequencing data from NL skin of 49 patients with acne (denoted as NL acne [NLA]) with those from 19 healthy controls with no acne history. We found 77 differentially expressed genes in NLA (log fold change > 1 ; $P < .05$), including genes associated with innate immunity and epidermal barrier function. Notably, KRT6C, KRT16, S100A8, S100A9, and lactotransferrin were upregulated, and LCE4A, LCE6A, and CTSE were downregulated. Gene set enrichment analysis revealed that metabolic pathways were enriched in NLA skin, whereas keratinization was negatively enriched. To identify compounds that could shift the gene expression signature of NLA skin toward healthy control skin, we performed connectivity mapping with the Library of Integrated Network-Based Signatures. We identified 187 compounds, particularly mTOR inhibitors, that could potentially normalize the gene expression profile of acne-prone skin to that of healthy skin. Our findings indicate that NLA skin has distinct differences in epidermal differentiation, cellular metabolism, and innate immunity that may promote lesion formation and suggest that mTOR inhibitors could restore NLA skin toward a healthier state, potentially reversing the predisposition to lesion development.

JID Innovations (2024);4:100306 [doi:10.1016/j.xjidi.2024.100306](https://doi.org/10.1016/j.xjidi.2024.100306)

INTRODUCTION

Acne vulgaris (acne) is a common, yet complex skin condition, that predominantly affects adolescents and young adults. The pathogenesis of acne remains only partially understood, with factors such as follicular hyperkeratinization, excess sebum production, colonization of the follicle by Cutibacterium acnes, and perifollicular inflammation contributing to its etiology [\(Gollnick, 2015](#page-11-0)). However, the molecular mechanisms underlying these processes, particularly in nonlesional (NL) skin, are less explored and could provide valuable insights into acne initiation and progression.

Many studies have underscored the significance of analyzing the skin's transcriptome to gain insights into dermatological conditions. Transcriptomic studies provide a comprehensive, unbiased overview of gene expression profiles that may contribute to disease phenotypes. In acne, analyzing the transcriptome of clinically normal NL skin could reveal predispositions to lesion formation and identify unique targets for therapeutic intervention. Although previous studies using gene expression microarrays did not find marked differences between NL skin from patients with acne and healthy controls (HCs), using more sensitive approaches, such as RNA sequencing (RNA-seq), with a larger sample size have the potential to unveil insights into the transcriptome of acne-prone skin (Kelhälä [et al, 2014](#page-11-1); [Trivedi et al, 2006](#page-12-0)).

This study leverages existing RNA-seq data to compare the transcriptome of NL skin from individuals with acne (denoted as NL acne [NLA]) with those from the healthy skin of individuals with no history of acne (Hall et al, 20[1](#page-0-2)9 $^{\rm 1)}$). By integrating differential gene expression analysis (DGEA), gene set enrichment analysis (GSEA), and transcription factor (TF) activity prediction, we identified alterations in biological pathways that are involved in epidermal differentiation, lipid metabolism, and innate immune responses in NLA skin. These findings not only highlight that NLA skin is distinct from healthy skin, but also suggest that such differences may prime the skin for lesion formation.

Furthermore, by employing a connectivity mapping approach, we identify compounds that can normalize/ restore the transcriptome of NLA skin. This exploratory study is crucial for developing additional therapeutics and may inform our understanding of individual susceptibility to acne, providing a foundation for more effective and perhaps preventative strategies for acne.

RESULTS

Study overview and sample demographics

We analyzed an existing RNA-seq dataset from both HC with no history of acne and NL skin of individuals with acne (NLA) to explore potential differences in gene expression (Hall et al, $2019¹$ $2019¹$ $2019¹$). The dataset consisted of full-thickness skin punch biopsy samples from the upper back of 19 HCs and 49 participants with NLA, including both males and females with acne [\(Figure 1](#page-2-0) and [Table 1](#page-3-0)). The NLA group had an average Investigator's Global Assessment score of 2, corresponding to mild-to-moderate acne severity. Age differences between the HC and NLA groups were not significant. Our comprehensive analysis encompassed DGEA, GSEA, TF activity prediction, and connectivity mapping [\(Figure 1](#page-2-0)). This thorough evaluation aimed to identify not only known acne-related factors such as hyperkeratinization, sebum production, and inflammation, but also to discover previously unknown associations through an unbiased approach. When performing the DGEA, we controlled for variables such as sequencing batch and sex to ensure that the observed gene expression differences were attributable to the tissue group (NLA or HC).

The transcriptome of patients with NLA differs from that of healthy individuals

Initially, we focused on global transcriptional differences in gene expression between HC and NLA skin by performing principal component analysis. This analysis revealed that HC and NLA skin distinctly separated along the first 2 principal components and clustered together by group, indicating global differences in the transcriptomes between these 2 groups ([Figure 2](#page-4-0)). Next, we performed DGEA to identify changes in gene expression that may promote acne lesion formation. This analysis identified a total of 367 genes that are differentially expressed between HC and NLA (141 upregulated, 226 downregulated) (log fold change > 0 , $P <$.05). Narrowing this differentially expressed gene list to include only those with an absolute log fold change >1 , we found 77 genes that exhibited the most significant change: 24 genes were upregulated, and 53 were downregulated in NLA skin compared with those in HC skin ([Figure 2](#page-4-0)) ($P < .05$).

Among the most significantly upregulated genes, we identified several with established roles in epidermal differentiation, innate immune response, and sebaceous gland biology—critical factors in acne pathogenesis. Notably, this group includes stress-related keratins KRT6C and KRT16, the calcium-binding proteins, S100A8 and S100A9, and lactotransferrin (LTF). In addition, MUC1, a marker of differentiated sebocytes, was upregulated. Conversely, our findings revealed a significant downregulation of genes associated with epidermal differentiation, including late cornified envelope proteins LCE4A and LCE6A, along with cathepsin E (CTSE). Furthermore, extracellular matrix genes, such as TNXB, PRG4, MFAP5, and MATN4, were downregulated. The detailed list of differentially expressed genes is available (Supplementary Material). Our DGEA indicates that the transcriptome of NLA skin differs from that of HC skin, suggesting that gene alterations in NLA skin may contribute to subsequent lesion formation.

GSEA identifies elevated metabolic activity in NLA skin

To explore the biological processes that were significantly enriched in NLA skin, we performed GSEA with the Hallmark and Reactome gene sets [\(Gillespie et al, 2022](#page-11-2); [Liberzon et al,](#page-11-3) [2015\)](#page-11-3). The analysis of the 50 Hallmark gene sets identified 17 that were positively enriched and 3 that were negatively enriched (adjusted $P < .01$) ([Figure 3](#page-5-0)). Gene sets associated with metabolic pathways, such as oxidative phosphorylation, fatty acid metabolism, glycolysis, and cholesterol homeostasis, were among the most positively enriched gene sets, suggesting an elevated state of metabolic activity in NLA skin. In addition, positive enrichment was noted for the mTORC1 signaling pathway, which is pivotal in regulating cell metabolism, survival, and proliferation ([Figure 3](#page-5-0)a and c). Positive enrichment was also observed for the IL-6-JAK-signal transducer and activator of transcription 3 (STAT3) signaling and inflammatory response gene sets, suggesting an enhanced immune activity in NLA skin. On the contrary, gene sets related to coagulation, UV response, and epithelial mesenchymal transition were negatively enriched.

GSEA using the Reactome gene sets provided additional granularity, enabling us to identify enrichment in skinspecific pathways. We found 23 Reactome gene sets that were positively enriched and 3 that were negatively enriched (adjusted $P < .01$) [\(Figure 3b](#page-5-0)). In examining the top positively enriched Reactome gene sets, we observed multiple metabolic and immune-related gene sets. This reinforces the idea of elevated metabolic and immune activity in NLA skin. Remarkably, the keratinization Reactome gene set was the most significantly negatively enriched ([Figure 3b](#page-5-0) and c). This set contains genes involved in the terminal differentiation of keratinocytes, suggesting a decreased keratinocyte differentiation profile in NLA skin. Furthermore, the negative enrichment in elastic fiber formation and extracellular matrix organization suggests decreased properties of the of the dermal matrix or epidermal basement membrane in NLA skin.

SREBP TFs are predicted to be key upstream regulators in NLA skin

To identify the drivers of the transcriptomic differences between NLA and healthy skin, we estimated the activity of TFs using the decoupler package with TF regulons from CollecTRI ([Badia-i-Mompel et al, 2022](#page-12-1); Müller-Dott et al, 2023). A total of 10 TFs were identified as significantly active in NLA skin. Notably, SREBF1 (SREBP1) and SREBF2 (SREBP2) exhibited the highest activity scores [\(Figure 4\)](#page-6-0). SREBP1 is predominantly involved in the regulation of genes for fatty acid synthesis, whereas SREBP2 regulates genes involved in cholesterol synthesis [\(Horton et al, 2003](#page-11-5); [Pai et al, 1998\)](#page-11-6). The expression and activity of both SREPB1 and SREBP2 have been linked with sebocyte lipogenesis and acne ([Harrison](#page-11-7) [et al, 2007](#page-11-7); [Li et al, 2023](#page-11-8); [Rosignoli et al, 2003](#page-12-2); [Smith](#page-12-3) [et al, 2008\)](#page-12-3). However, SREBP activity and function have not been previously associated with NLA skin.

Figure 1. Summarized demographic information of study participants and schematic of study design. (a) Whole skin punch biopsies (4 mm) were collected from the upper back of 49 individuals with acne (NLA) and 19 controls with no history of acne (HC). Biopsies from the NLA group were collected from nonlesional skin that was at least 5 cm away from any active lesion. The table shows the number of male and female participants, mean age, and mean acne Investigator's Global Assessment score. (b) After RNA isolation from the biopsies, RNA-seq and subsequent analyses were performed. These included differential gene expression analysis, gene set enrichment analysis, TF activity prediction, and connectivity mapping to identify factors that distinguish NLA from HC skin and potential acne therapeutics. HC, healthy control; NLA, nonlesional acne; RNA-seq, RNA-sequencing; TF, transcription factor.

Connectivity mapping highlights mTOR inhibitors as candidates for acne intervention

The primary objective of acne therapy is to prevent the emergence of new lesions. To this end, we compared the gene expression signature (GES) of NLA skin with the chemical perturbagen signatures from the Library of Integrated Network-based Cellular Signatures (LINCS) ([Subramanian et al, 2017](#page-12-4)). This was done to uncover potential therapeutic agents for acne. The GES for NLA skin comprised all differentially expressed genes (adjusted P < .05). This GES was compared against chemical perturbation signatures within LINCS to identify compounds that could normalize the gene expression of NLA skin toward that of healthy skin. Our analysis identified 187 compounds with the potential to correct the abnormal gene expression of NLA skin (reversing compounds) (normalized connectivity score <-1) and 178 compounds that could replicate the gene expression profile of NLA skin (mimicking compounds) (normalized connectivity score > 1) ([Figure 5\)](#page-7-0). Interestingly, among the reversing compounds, several are currently utilized or have been explored for acne treatment, such as tretinoin and calcipotriol [\(Mahran et al, 2024;](#page-11-9) [Reynolds et al, 2024\)](#page-12-5). In contrast, the mimicking compounds include compounds such as glucocorticoid and androgen receptor agonists, which induce acne ([Arora et al, 2011](#page-11-10)).

Further enrichment analysis of the ranked compounds identified over-represented drug classes and targets. Notably, drug targets such as mTOR, PIK3CA, ATP1A1, and TUBB emerged as significantly over-represented among the reversing compounds. Conversely, the target NR3C1, a glucocorticoid receptor, was enriched in the mimicking compound group [\(Figure 5\)](#page-7-0). This suggests a therapeutic potential for compounds targeting mTOR and PI3K signaling pathways in reversing the gene expression alterations of NLA skin. However, it also suggests caution with glucocorticoid receptor agonists because their effects on gene expression are similar to those observed in NLA skin.

To validate our connectivity mapping findings, we searched the National Center for Biotechnology Information Gene Expression Omnibus for public skin transcriptome datasets examining the effects of compounds or drug classes highlighted in [Figure 5b](#page-7-0) and c. We identified 2 RNA-seq datasets: one evaluating the mTOR inhibitor rapamycin in mouse skin (GSE147950) and another evaluating the glucocorticoid receptor agonist clobetasol propionate in human skin (GSE120783) (additional details are provided in Materials and Methods). We compared the top Hallmark GSEA results from NLA skin with these datasets, representing reversing (rapamycin) and mimicking (clobetasol propionate) compounds. The comparison with clobetasol propionate revealed shared positively enriched gene sets, such as adipogenesis and fatty acid metabolism, showcasing that topical clobetasol can induce gene signatures similar to those of NLA skin. These findings are supported by the known adverse events associated with glucocorticoid use, including acneiform eruptions. In contrast, the NLA comparison with rapamycin identified several gene sets that were oppositely enriched, including oxidative phosphorylation, fatty acid metabolism, mTORC1 signaling, glycolysis, and cholesterol homeostasis, making it plausible that rapamycin may have similar effects in human skin. Epithelial-mesenchymal transition was negatively enriched in all comparisons ([Figure 5](#page-7-0)f). Together, these comparative GSEA analyses support our computational approach to drug repurposing for identifying potential acne therapies. However, given the limited number of comparable datasets (each with their own limitations), experimental validation is essential in future studies.

Transcriptomic Analyses in Acne-Prone Skin

DISCUSSION

In this study, we elucidated the transcriptomic differences between the individuals with NLA and HCs with no history of acne. By integrating DGEA, GSEA, and TF activity prediction, we uncovered pronounced differences in epidermal differentiation, cellular metabolism, and innate immune responses in NLA skin ([Figure 6](#page-8-0)). These findings suggest that NLA skin possesses intrinsic molecular characteristics that may promote acne lesion formation. Furthermore, we applied connectivity mapping techniques to identify compounds that could potentially restore NLA skin to a healthier state.

Our findings indicate that even clinically normalappearing NLA skin exhibits signs of epidermal stress, as evidenced by the significant upregulation of stress-related keratins such as KRT6C and KRT16, along with damageassociated molecular patterns such as S100A8 and S100A9. Typically, KRT6 and KRT16 expression is localized to glabrous skin and the outer root sheath of hair follicles, yet their expression increases in the interfollicular epidermis after injury or in inflammatory skin diseases [\(Lessard et al, 2013](#page-11-11); [Zhang et al, 2019;](#page-12-6) [Zouboulis et al, 2020](#page-12-7)). A recent analysis of single-cell transcriptomic data from various skin conditions, including psoriasis and hidradenitis suppurativa, revealed that the presence of stress keratins such as KRT6 and KRT16 in lesional skin points to a shift in keratinocyte differentiation. This shift is associated with elevated expression of genes involved in innate immune function [\(Cohen et al, 2024](#page-11-12)). In line with this association, we observed a significant decrease in the enrichment of the Reactome keratinization gene set, which includes genes involved in keratinocyte differentiation and development of the epidermal barrier, suggesting that these processes are impaired in NLA skin. This impairment is similar to what has been previously observed in lesional acne skin, highlighting barrier dysfunction as a pathologic feature of acne ([Dull et al, 2023](#page-11-13)). Our findings broaden this context to NL skin and suggest that impaired epidermal barrier function could predispose the skin to lesion formation. Although acne is not typically associated with overt epidermal barrier defects, functional studies of lesional acne skin have demonstrated increased transepidermal water loss and decreased levels of ceramides in the stratum corneum ([Pappas et al, 2018](#page-11-14); [Yamamoto et al, 1995\)](#page-12-8).

Given the link between acne and impaired epidermal barrier function, the upregulation of genes encoding

antimicrobial peptides such as the S100 proteins and lactotransferrin could reflect an activation of the innate immune response to skin commensals such as C. acnes. The proteins S100A8 and S100A9 form the calprotectin complex, which inhibits microbial activity by chelating manganese (II) ion and zinc (II) ion ([Damo et al, 2013](#page-11-15)). Lactotransferrin, a multifunctional protein, not only sequesters ferric ion to prevent bacterial iron acquisition but also interacts with the bacterial cell surface through its affinity for negatively charged molecules, either causing membrane damage or inhibiting bacterial adhesion to host cells (González-Chávez [et al, 2009\)](#page-11-16). The involvement of these proteins in acne has

been reported in previous studies. For instance, [Fouda et al](#page-11-17) [\(2021\)](#page-11-17) found higher serum calprotectin levels in patients with acne, correlating with acne severity. Elevated expression of S100A9 in acne lesions and increased lactotransferrin in follicular casts from acne skin relative to that in control skin have been reported ([Bek-Thomsen et al, 2014](#page-11-18); Kelhälä et al, [2014;](#page-11-1) [Trivedi et al, 2006\)](#page-12-0). S100A8/S100A9 proteins are

expressed by immune cells and by keratinocytes in response to wounding or inflammation ([Kerkhoff et al, 2012\)](#page-11-19). Lactotransferrin is present in many body secretions, is an estrogenresponsive gene, and can be induced by innate triggers such as lipopolysaccharide or double-stranded RNA [\(Cao et al,](#page-11-20) [2022;](#page-11-20) [Li et al, 2009](#page-11-21)). Although their precise role in acne is not well-understood, the upregulation of these molecules

Transcriptomic Analyses in Acne-Prone Skin

Figure 4. TF activity prediction suggests significant activation of SREBF1 and SREBF2 in NLA skin. (a) All TFs with predicted differential activity in NLA skin relative to those in healthy skin using the univariate linear model method from the decoupleR package (adjusted $P < .01$). (b) Volcano plots showing patterns of expression for SREBF2/SREBF1 regulated genes. Colors show the predicted effect of each TF-gene interaction from CollecTRI, with orange and blue indicating activation and repression of gene expression, respectively. supports a possible role in barrier disruption and innate immune activation in NLA skin.

The positive enrichment of gene sets related to lipid metabolism, glycolysis, and oxidative phosphorylation in our study suggests a compensatory mechanism by NLA skin to restore epidermal barrier properties in response to disrupted barrier processes. This aligns with the well-established link between compromised epidermal barrier function and the upregulation of lipid biosynthesis [\(Harris et al, 1997;](#page-11-22) [Menon](#page-11-23) [et al, 1985](#page-11-23); [Proksch et al, 1993](#page-12-9)). Specifically, the increased synthesis of ceramides, cholesterol, and fatty acids, which are essential components of the epidermal barrier, serves as a reparative mechanism after barrier disruptions. The predicted increase in the activities of SREBP1 and SREBP2, key transcriptional regulators for the synthesis of fatty acid and cholesterol, respectively, lends further support to this hypothesis [\(Horton et al, 2003](#page-11-5); [Pai et al, 1998\)](#page-11-6). In addition, the gene set enrichment in lipid metabolism and the predicted activity of SREBP1 might also contribute to increased sebum production, a critical factor in acne pathogenesis. SREBP1 is expressed in sebaceous glands and activates lipogenesis, in vitro, in the SEB-1 sebocyte cell line ([Harrison et al, 2007](#page-11-7); [Smith et al, 2008,](#page-12-3) [2006](#page-12-10)). In a study by [Smith et al \(2008\)](#page-12-3), treatment of SEB-1 sebocytes with IGF1 led to SREBP1 activation and lipogenesis through the PI3-kinase (PI3K)/Akt signaling pathway. The roles of SREBP1 and SREBP2 in lipid metabolism and their association with sebocyte lipogenesis highlight a crucial link between lipid metabolism dysregulation and acne, suggesting that targeting these TFs or their downstream pathways could offer unique therapeutic strategies.

We found that mTORC1 signaling, which bridges PI3K/Akt signaling and SREBP1-mediated lipogenesis, was positively enriched in NLA skin ([Porstmann et al, 2008\)](#page-12-11). The connection between mTORC1 signaling and acne pathogenesis has been proposed previously, but empirical evidence from patient tissue is limited [\(Melnik, 2018\)](#page-11-24). [Lembo et al \(2020\)](#page-11-25) found increased mTOR gene expression in lesional acne skin, and [Monfrecola et al \(2016\)](#page-11-26) demonstrated an increase in immunofluorescence staining intensity for phospho-S6 kinase 1, a key mTORC1 target, in both NL and lesional skin from patients with acne compared with that from HCs. Our finding of mTORC1 signaling enrichment in NLA skin strengthens the hypothesis that mTORC1 plays a role in acne pathogenesis.

Our connectivity mapping analysis further underscores the role of increased mTOR activity in acne, revealing that mTOR inhibitors are over-represented among reversing compounds capable of restoring NLA skin to a healthier state. This indicates the potential of mTOR inhibitors as an innovative therapeutic strategy for acne, particularly in a topical formulation. For example, rapamycin, known for its selective inhibition of mTORC1, has been effectively used in topical treatment of facial angiofibromas in patients with tuberous sclerosis complex, demonstrating a strong safety profile with

Transcriptomic Analyses in Acne-Prone Skin

Figure 5. Connectivity mapping identified mTOR inhibitors as potential therapeutic candidates to reverse acne skin signature. (a) Workflow for compound prioritization: the similarity of the acne-prone disease signature (genes differentially expressed between NLA and HC) and LINCS signatures for chemical perturbagens with an annotated mechanism of action was calculated. There were 187 compounds that could potentially shift NLA gene expression toward HC (reversing; adjusted $P < .01$, normalized connectivity score <-1) and 178 compounds that could potentially shift HC gene expression toward NLA (mimicking; adjusted $P < .01$, normalized connectivity score > 1). Additional enrichment analysis was performed to identify over-represented drug classes among reversing and mimicking compounds. (b, c) Plots showing the top 10 reversing and mimicking compounds. The y-axes show the unique perturbagen identifier with the common name in parentheses. Mechanisms of action are annotated on the plot. (d, e) Significantly enriched compound targets and drug classes (adjusted P < .01). (f) Comparative Hallmark GSEA results for this study (NLA) alongside those from public skin datasets GSE147950 (Rapa treated vs control mice) and GSE120783 (CBP treated vs untreated human skin). These public datasets are examples of a top reversing compound (mTOR inhibitor: rapa) or mimicking (glucocorticoid receptor agonist: CBP) compound. GSEA was performed separately for each indicted comparison. *P < .05, **P < .01, and ***P < .001. negligible systemic absorption and minimal adverse effects ([Aitken et al, 2023](#page-11-27); [Koenig et al, 2018\)](#page-11-28). In addition, topical rapamycin has proven effective and well-tolerated in treating rosacea, which shares several pathological similarities with acne [\(Deng et al, 2021](#page-11-29)). In the study by [Deng et al \(2021\)](#page-11-29), mTORC1 was shown to be activated in the lesional skin of patients with rosacea relative to that in HCs. Twice-daily application of topical rapamycin over 4 weeks resulted in significant clinical improvement in rosacea symptoms, underscoring the therapeutic promise of mTOR inhibition in skin conditions akin to acne.

Limitations

This study employed a comprehensive, unbiased computational approach to investigate the transcriptome of NLA skin and identify possible therapeutic targets. However, the absence of matched patient biopsies limited our ability to confirm the correlation between transcriptomic findings and protein expression in the skin. In addition, our connectivity mapping analysis was limited to LINCS compounds with known mechanisms of action, with the goal of identifying clinically relevant compounds. Exploring LINCS compounds with unknown mechanisms could broaden the spectrum of potential compounds but would require additional in vitro experiments or computational analysis to elucidate their effects. We used publicly available datasets for comparative GSEA analyses with NLA skin, recognizing the limitations, including different species, low sample number, and incomplete metadata, for an initial assessment to understand how identified compounds may impact acne skin. Importantly, experimental validation of the compounds identified by this drug repurposing analysis is necessary in future studies. Despite these challenges, analyzing data from nearly 70 HCs and patients with acne has unveiled previously unknown transcriptomic changes in acne-prone skin. This allows for the generation of hypotheses about key genes, pathways, and mechanisms involved in acne pathogenesis.

NL skin from individuals with acne shows significant transcriptomic differences from that of HCs, potentially making it more susceptible to developing acne lesions. Our analyses explored both established acne-related processes, such as hyperkeratinization, sebum production, and inflammation, and adopted an unbiased approach to uncover factors associated with acne onset. We discovered that in NLA skin, processes related to epidermal differentiation and cellular metabolism are altered in ways that potentially could affect the pilosebaceous unit, leading to acne lesions. Notably, our findings indicate an increase in mTORC1 signaling in NLA skin, suggesting that mTOR inhibitors could be promising agents for preventing lesion formation. Understanding these transcriptomic alterations, especially the potential role of mTOR inhibitors, opens new avenues for developing additional therapeutics to combat acne.

MATERIALS AND METHODS

RNA-seq data

Full-thickness human skin samples (4-mm punch biopsies) were obtained from the upper back of patients with mild-to-moderate acne and healthy volunteers in 2016 under an institutional review board-approved protocol (IF1719992; Mount Sinai School of Medicine) after written informed consent (Hall et al, 2019¹). This previous study included 20 adults without a history of acne and 56 adults with mild-to-moderate acne. We performed a de novo RNAseq analyses from NLA and HC skin using this original dataset (Hall et al, 20[1](#page-0-2)9¹). The NLA biopsies were collected from areas at least 5mm distant from any active acne lesion. Our de novo analysis included samples with sufficient reads from a single sequencing run to minimize batch effects, ultimately incorporating data from 49 NLA and 19 HC samples [\(Table 1\)](#page-3-0).

Processing of RNA-seq data

Quality control and trimming of FASTQ files were performed using fastp [\(Chen et al., 2018\)](#page-11-30). Read mapping and transcript quantification were performed using Salmon, with human genome and transcriptome files obtained from Ensembl (assembly GRCh38.14;

A total of 7454 genes were differentially expressed between topical CBP and Unt skin (log₂ fold change > 0; adjusted $P < .05$). (c, d) GSEA using Hallmark gene sets from the molecular signatures database revealed 20 and 21 significantly enriched gene sets for the Rapa and Con and CBP and Unt comparisons, respectively (adjusted $P < .05$). CBP, clobetasol propionate treatment; Con, control; GSEA, gene set enrichment analysis; NS, not significant; PC, principal component; PCA, principal component analysis; Rapa, rapamycin; Unt, untreated.

release 109) [\(Martin et al, 2023;](#page-11-31) [Patro et al, 2017\)](#page-11-32). Gene-level counts were generated using the tximport package in R ([Soneson](#page-12-12) [et al, 2015\)](#page-12-12).

DGEA and GSEA

We used the principal components analysis tools package for R to perform principal components analysis on the normalized count matrix ([Blighe and Lun, 2024\)](#page-11-33). DGEA was conducted with edgeR and limma-voom ([Law et al, 2014;](#page-11-34) [McCarthy et al, 2012\)](#page-11-35). Multiple comparisons adjustment of P-values was performed using the default Benjamini-Hochberg method in the Limma topTable function. The top differentially expressed genes (adjusted $P < .05$, absolute log fold change > 1) were used for heatmap generation using the ComplexHeatmap package ([Gu, 2022\)](#page-11-36). The list of differentially expressed genes, ranked by the moderated t-statistic, served as input for GSEA. GSEA was performed using the fGSEA package with the Hallmark and Reactome gene set collections sourced from the molecular signatures database (version 7.5.1) through the msigdbr package ([Dolgalev, 2022](#page-11-37); [Gillespie et al, 2022](#page-11-2); Korotkevich et al, $2021²$ $2021²$; [Liberzon et al, 2015](#page-11-3); [Subramanian et al, 2005\)](#page-12-13). Gene sets with adjusted $P < .01$ were considered significantly enriched. We utilized the collapsePathways function from the FGSEA package to select independent Reactome pathways.

TF enrichment analyses

Estimation of TF activity was performed using the univariate linear model method from the decoupler package for R, with weighted TF regulons from CollecTRI ([Badia-i-Mompel et al, 2022;](#page-12-1) Müller-Dott [et al, 2023](#page-11-4)). We estimated aggregate differences in TF activity by running the univariate linear model on the list of genes output by the differential expression analysis ranked by the moderated t-statistic. We analyzed TFs with >20 annotated targets and used the Benjamini-Hochberg method for multiple comparisons adjustment. TFs with an adjusted $P < .01$ were considered significant.

Computational drug repurposing

Retrieval and processing of chemical perturbagen signatures. To discover compounds with potential therapeutic value for acne, we utilized the LINCS to perform connectivity mapping [\(Subramanian et al,](#page-12-4) [2017\)](#page-12-4). We downloaded the level 5 chemical perturbation signatures and the associated metadata from the LINCS project from <https://clue.io> [\(Clue Data, 2020\)](#page-11-38). Using the metadata, we filtered signatures to those that were from compounds with a known mechanism of action, were high quality (is_hiq = 1), and were exemplar (is_exemplar = 1) for a specific perturbagen and cell type. We limited our analysis to signatures from the 24-hour time point. In instances where multiple perturbagen doses for a given cell line were available, we retained the signature corresponding to the dose that induced the strongest transcriptional response, measured by the transcriptional activity score.

Constructing a query disease signature and connectivity mapping. To create a GES for NLA skin, we conducted a separate differential expression analysis of NLA versus healthy skin that was restricted to the Best INferred Genes gene space. Lists of upregulated and downregulated genes (adjusted $P < .05$) were used as input for the LINCS enrichment algorithm. We utilized the LINCS enrichment algorithm, as implemented in the signatureSearch R package, to calculate the similarity between our NLA acne skin signature and the perturbagen signatures ([Duan et al., 2020\)](#page-11-39). Compounds were considered significant if the weighted connectivity score had a false discovery rate <.01. Compounds with a negative weighted connectivity score (reversers) can shift the GES of NLA toward healthy, and compounds with a positive weighted connectivity score (mimickers) can shift the GES from healthy toward NLA.

Drug classes and target enrichment analysis. Further enrichment analysis was performed to identify drug classes and drug targets that were overrepresented among the compounds correlating with our disease signature. Drug sets and target sets were constructed by collapsing LINCS annotations according to their respective perturbagen_id. Compounds were ranked by their cell line collapsed enrichment score (normalized connectivity score summarized across cell type). The FGSEA package was utilized to compute the enrichment statistics. Drug classes and targets were considered with an adjusted $P < .01$.

This methodology enabled us to discern compounds that could potentially revert the transcriptional changes associated with NLA skin back to a state resembling HC skin, thereby identifying candidate molecules for further investigation as acne treatments.

Comparison with public datasets. To begin validation of our computational approach and predictions, we compared our data with publicly available datasets. We searched Gene Expression Omnibus [\(https://www.ncbi.nlm.nih.gov/geo/](https://www.ncbi.nlm.nih.gov/geo/)) for human or murine skin datasets (microarray or RNA-seq) that investigated any of the top 10 mimicking or reversing compounds or drug classes [\(Figure 5b](#page-7-0) and c). We identified 2 RNA-seq datasets—one evaluating the mTOR inhibitor rapamycin in mouse skin (GSE147950) and another evaluating the glucocorticoid receptor agonist clobetasol propionate in human skin (GSE120783)—and obtained the tables of raw gene counts from Gene Expression Omnibus. GSE147950 contained mouse skin data from Rapa-treated BALB/c mice (intraperitoneal injection; 4 mg/kg, 5 days; $n = 3$) and control mice $(n = 3)$ [\(Deng et al, 2021,](#page-11-29) [2015](#page-11-40)). GSE120783 contained human skin data from a study where 0.05% topical clobetasol propionate was applied to the right arm of healthy subjects, and paired biopsies were collected from the right (treated) and left (untreated) arms after 24 hours ($n = 17$ subjects) [\(Sarkar et al, 2017](#page-12-14)). We performed differential expression analysis, accounting for the paired samples in GSE120783 and GSEA using the same methods as stated earlier [\(Figure 7\)](#page-9-0). We then compared gene set enrichment results from these public data with those of the NLA skin to identify any pathways that were concordantly or discordantly enriched.

ETHICS STATEMENT

RNA-sequencing data were previously generated following institutional review board-approved protocols ((IF1719992; Mount Sinai School of Medicine)) for human subjects as described in Hall et al $(2019¹)$.

DATA AVAILABILITY STATEMENT

RNA-sequencing data analyzed in this article can be found at [https://www.](https://www.ncbi.nlm.nih.gov/bioproject/?term=PRJNA1114663) [ncbi.nlm.nih.gov/bioproject/?term](https://www.ncbi.nlm.nih.gov/bioproject/?term=PRJNA1114663)=[PRJNA1114663](https://www.ncbi.nlm.nih.gov/bioproject/?term=PRJNA1114663), hosted at the Sequence Read Archive.
