Introduction

Malignancy following renal transplantation is an uncommon consequence of long-term suppression of anti-tumour immune surveillance, but seems to be increasing in incidence with improved survival of renal transplant recipients.[1] The incidence of malignancy is markedly elevated in renal transplant recipients compared to the general population; however, little is known about their prognosis and the contribution of immunosuppression to disease progression. We report on the clinical course of a pancreas-kidney transplant recipient who developed invasive renal allograft-derived neuroendocrine carcinoma with rapid post-nephrectomy metastatic progression.

Case report

A 48-year-old gentleman developed gross hematuria approximately 7 years after simultaneous pancreas-kidney transplant for diabetic nephropathy. He had normal renal and pancreatic allograft function on immunosuppression with tacrolimus, mycophenolate, and prednisone. An ultrasound of both native kidneys and renal allograft was normal. Cystoscopy revealed a vascular lesion on the left lateral wall that was later resected, revealing a grade 2/3 papillary Ta urothelial carcinoma (UC).

The patient continued to have gross hematuria despite normal cystoscopy. CT urogram demonstrated hyperdense debris in the transplant collecting system suggestive of clot versus Post-transplant Lymphoproliferative Disorder (Fig. 1). Retrograde pyelogram revealed a lower pole filling defect in the transplant kidney and selective cytology showed atypical urothelial cells. Flexible ureteroscopy of the transplant kidney was unsuccessful. The suspicious upper tract lesion was biopsied percutaneously revealing mixed invasive UC with a small-cell component. Metastatic work-up at this time including MRI abdomen/pelvis and CT chest was negative.

Transplant nephroureterectomy revealed pT3 small-cell/high-grade UC and genotyping confirmed this to be of donor origin (Fig. 2). Two months post-op, the patient again developed gross hematuria secondary to a large anterior bladder tumour recurrence, which was resected and shown to be high-grade T1 disease with mixed small cell and UC features. Neadjuvant chemotherapy was deferred due to the potential risks in a transplant patient, and radical cystectomy with bilateral native nephrectomies was performed. The pathologic specimen revealed only a few foci of bladder carcinoma *in situ* and normal kidneys.

Five months after cystectomy, a surveillance CT scan revealed local recurrence in the allograft fossa, hepatic metastases, and retroperitoneal lymphadenopathy. Immunosuppression had been maintained up to this point in order to preserve pancreatic allograft function, but at this point it was discontinued. Follow-up CT scan after 3 months showed interval progression of hepatic metastases (Fig. 3). The patient's pancreatic allograft also began to fail at this point, and he was started back on insulin.

Systemic cisplatin/gemcitabine chemotherapy was initiated with complete resolution of all metastases after 6 cycles. He remained free of

disease 12-months after completing chemotherapy.

Discussion

The incidence of any malignancy following renal transplant is estimated to be 7.5% at 3 years, while the risk of UC ranges from 0.02% to 1.0% (~3-fold that of the general population).[1] Factors associated with post-transplant UC include length of immunosuppression and origin of allograft from a deceased donor, as well as the usual risk factors.[2] No particular immunosuppressive regimen appears to be associated with heightened risk of malignancy. Most patients present with hematuria.

The literature on metastatic UC post-transplant is sparse and mostly limited to isolated case reports. Our case is unique in that it is complicated by the pancreatic allograft, aggressive histology, extensive metastatic disease, and the challenges of chemotherapy on dialysis. Most reported cases of allograft-derived UC are localized and managed by transplant nephroureterectomy with good oncological outcomes.[3] However, these patients are usually discontinued on their immunosuppression unlike our patient because of his pancreatic graft. This likely hindered his ability to mount an alloimmune response against any residual tumour post-operatively. The role of alloimmunity in the clearance of donor-origin tumours is apparent in a retrospective review of patients with allograft-derived malignancies by Penn et al.[4] It was shown that 18/33 patients with metastatic renal allograft tumour (of unspecified histology) achieved complete remission with transplant nephrectomy and discontinuation of immunosuppression. Unfortunately, it appears that the rate of immune recovery was insufficient in our case, as evidenced by the 3-month delay in the failure of his pancreatic allograft.

Unfortunately, our patient progressed to metastatic disease despite removal of the allograft and native urinary tract, and stopping immunosuppression. Cisplatin-gemcitabine was started since the tumour histology was predominately high-grade UC, and this was thought to be a more tolerable regimen in a dialysis patient. Given the challenges of dosing chemotherapy on dialysis, we avoided neoadjuvant or adjuvant chemotherapy earlier in the disease course, and in the metastatic setting opted for a trial of discontinuing immunosuppression before attempting chemotherapy. The pancreatic graft was left *in situ* as the risk of pancreatitis was outweighed by the threat of metastatic disease in

delaying potential systemic therapy while waiting for allograft explantation.

It is well known that transplant patients are at much higher risk for progression of any malignancy.[5] In line with this, our case developed rapid recurrences and eventual progression to metastatic disease. A critical step in the management of renal transplant patients with allograft malignancy is determining the source of the index lesion. Although most urologic malignancies post-transplant are from the native tract, a donor cancer should be treated with transplant nephroureterectomy and early discontinuation of immunosuppression, if permissible.

Conclusion

In summary, we have described a case of metastatic UC in a patient with simultaneous pancreas-kidney transplant. While a relatively rare event, donor-derived malignancy is likely to be experienced at some point by renal transplant centres and requires careful management due to higher risk of progression and attention to unique factors such as alloimmunity.
