Abstract

Purpose Transvaginal cervical length measurement in women with symptoms of preterm labor has been used to decide if treatment is necessary. Cervical length measurement may also have additional effects on patients, such as providing reassurance, although the evidence to support this is unclear. We explored and summarized to what extent additional effects of cervical length measurement in women with threatened preterm labor have been reported in the clinical literature and what the magnitude of these effects was.

Methods We performed a systematic review of the literature to identify articles reporting on cervical length measurements in women with symptoms of preterm labor. We assessed whether these articles reported patient outcomes other than preterm delivery.

Results The electronic and hand search resulted in 764 articles, of which 172 met initial criteria for further eligibility assessment. We found 12 articles that reported additional effects of cervical length measurement in symptomatic women, such as the reassurance or the sensory consequences related to the transvaginal procedure. None of the articles quantified such additional effects.

Conclusions There appears to be a gap between the presumed effects of cervical length measurement on patient outcomes, such as patients' reassurance, and the actual assessment of these effects during test evaluations. We suggest that future evaluations of prognostic preterm labor tests include a comprehensive assessment of patient outcomes.

Introduction

In pregnant women with symptoms of preterm labor, prediction of imminent preterm delivery is of utmost importance. This information can be used to decide on tocolytics and administration of corticosteroids, and allows timely transfer to perinatal centers. Whether cervical length measurement provides benefit for these women has been a recurrent topic of study. In general, women with a short cervix are at higher risk for preterm delivery than women with a long cervix. If the cervix is of sufficient length, the chance of imminent preterm delivery is low, and hospitalization or therapy of women otherwise considered at-risk may be avoided. Consequently, a number of studies have evaluated the prognostic accuracy of this test with respect to predicting preterm delivery [1].

As women with preterm contractions are often worried that these contractions represent actual preterm labor, physicians also may use cervical length measurement to reassure pregnant women whose cervix is not shortened. Since the image of cervical ultrasound is visually illustrative to patients, this test is believed to enhance reassurance.

It has been shown for a variety of tests that their results may have additional effects on patients other than guiding clinical management decisions. [2] These additional effects may also be an important reason for physicians to order a test [3]. However, it is unclear to what extent reassurance and other psychological effects on patients have been documented in evaluations of cervical length measurement. It is possible that the intended effect of reassuring worried women is not achieved in clinical practice, and that cervical length measurement actually induces anxiety rather than relieves uncertainty [4].

We have performed a systematic review of the literature to explore and summarize to what extent effects beyond the prognostic accuracy or therapeutic ramifications of cervical length measurement in women with preterm contractions have been reported, and to obtain the estimates of the magnitude of these effects.

Methods

We performed an electronic search on PubMed using the following search strategy: (cervical length measurement [Mesh] OR (cervi* [tiab] AND (length [tiab] OR ultrasongraphy [Mesh] OR measurem*[tiab] OR ultrasound[tiab] OR echo[tiab])) AND ((preterm* [tiab] OR premat* [tiab]) AND (parturition [Mesh] OR parturit* [tiab] OR birth [tiab] OR labor [tiab] OR labour [tiab] OR newborn*[tiab] OR infant[tiab])) OR obstetric labor, premature [Mesh] OR premature birth [Mesh] OR infant, premature [Mesh]). In addition, we searched the reference lists of identified articles for additional studies. We applied no exclusion criteria, and thus all study designs and languages were eligible for inclusion.

Article selection was performed independently by two authors (JV and RK). The articles resulting from the electronic search initially were screened based on titles and abstracts. All articles that evaluated cervical length measurement in women with threatened preterm contractions were selected for further evaluation and full-text assessments were made. Discrepancies in article selection were resolved by achieving consensus through discussions.

All articles selected for full-text assessment were studied in detail. For the final analysis we included all articles that reported or mentioned any additional effects of the transvaginal cervical length measurement. Characteristics of the articles (e.g. type of study design, year of publication) were extracted. Further, we evaluated the type of patient outcome that was reported, whether this additional effect was measured or merely mentioned, whether these measurements were quantitative or qualitative, and, if they were quantitative, what the magnitude of the effect was.

Results

The electronic search yielded 756 articles. The additional hand search resulted in eight additional articles being identified. Of these 764 articles, 194 (25%) articles were selected based on the title and abstract for full-text assessment. However, 22 articles could not be included because no full text was available in The Netherlands. Nevertheless, the abstracts of these 22 articles did not discuss any additional effects of the transvaginal cervical length measurement.

Of the 172 articles that could be studied, 97 reported on the accuracy of preterm labor tests, of which 70 in particular about cervical length measurement in women with preterm labor. We found 25 articles that described additional effects of preterm labor tests. Thirteen of these articles were not related to transvaginal cervical length measurement: four described additional effects of fetal fibronectin tests [4–7] of which one article measured maternal anxiety by questionnaires [5], eight described additional psychosocial effects in women without symptoms of preterm labor [8–15] of which most focused on the acceptability of the transvaginal procedure, and one paper described additional psychosocial effects related to translabial, but not transvaginal, ultrasonography [16] (Table 1). Thus, 12 articles described additional effects of the cervical length measurement in women with threatened preterm labor and were eligible for further analysis (Table 2, Fig. 1).

The provision of reassurance as an additional consequence of the cervical length measurement in women with threatened preterm labor was described in one before-and-after-measurement study by Sanin-Blair et al. [17]. In the discussion section of the article the authors suggested that cervical length measurement might give more reassurance to both women with symptoms of preterm labor and their physicians in comparison to digital examinations due to its numerical result. However, no data were provided to support this concept. One cohort study by Holst et al. [18] noted in the discussion section that false positive cervical length measurements could lead to ‘psychological costs’, although did not provide any further reference or specification on what these costs entailed or how they should be measured.

More frequently, additional sensory effects of the procedure of transvaginal ultrasound were discussed, although these effects were not related to the actual result of the cervical length measurement. The magnitude of this additional effect was reported in one descriptive series [19]. Based on a questionnaire survey in pregnant women at 23 weeks of gestation, the authors stated that only 2% of women reported pain or severe discomfort during the transvaginal ultrasound procedure [9]. Of these articles, one cohort study reported that transvaginal cervical length measurement was better tolerated than digital exams [27]. This statement was supported by a remark in a letter (specifically an author's reply to a letter to the editor) [24] and by a qualitative review [20] referring

to a study that assessed pain scores of transvaginal ultrasound and digital exams in women undergoing induction of labor [28]. In addition, three review papers [23, 25, 26] and one cohort study [22] stated that transvaginal cervical length measurement was acceptable for patients. Three of these articles referred to questionnaire surveys that had assessed the acceptability of transvaginal ultrasound in the

first or second trimester of pregnancy [9, 10, 13, 29]. In contrast, one qualitative review noted patients' reticence to have transvaginal ultrasound performed, but did not provide further details [21].

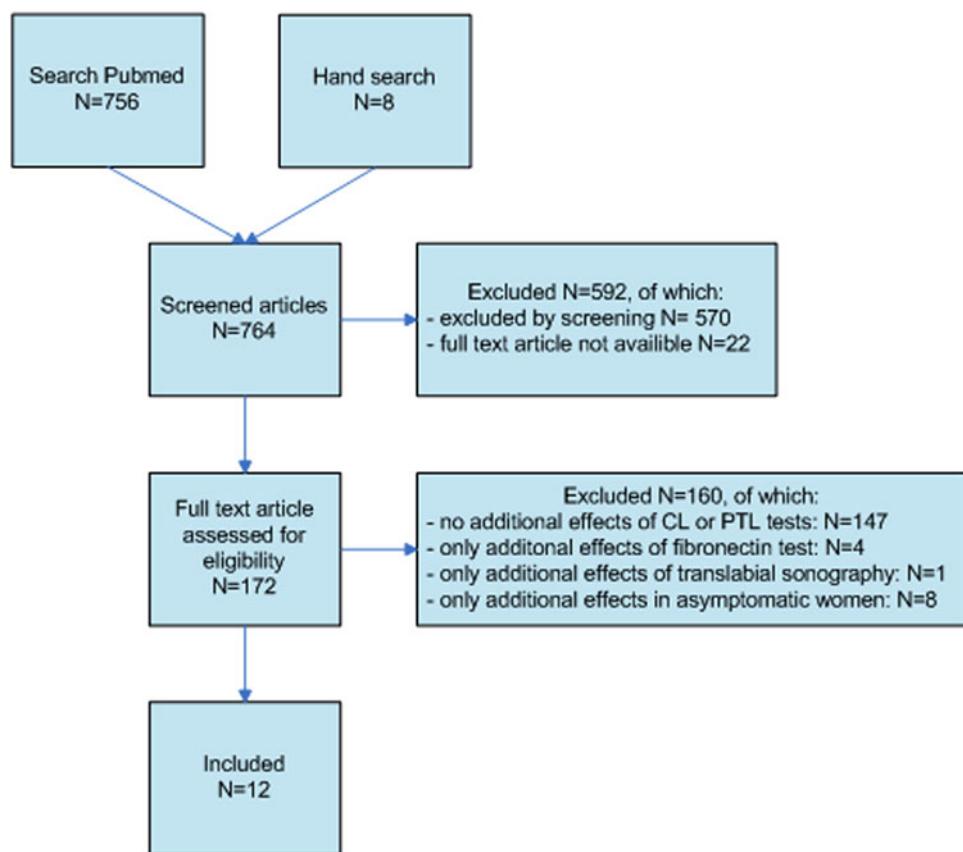

One descriptive review mentioned that the performance of cervical length measurements could enhance patient satisfaction with the health care system, without specifying a mechanism for or quantifying this enhancement [26]. One cohort study stated that, in general, the false positive results of the cervical length measurement could lead to financial costs of families, although no data were provided to demonstrate this possibility [18]. Finally, one systematic review stated that patients (and physicians) would prefer any extra test that would enhance efficacy, without offering further explanation what that efficacy entailed [30].

Discussion

This systematic review shows that test evaluations of cervical length measurements in women with threatened preterm labor have not yet integrated patient-centered outcomes beyond preterm delivery. We did not find a single study that had measured the psychosocial effects of performing a cervical length measurement in women with symptoms of preterm labor. In contrast, such additional effects were considered relevant by several authors, who often referred to them in the discussion section of their articles.

This review illustrates that empirical evidence about an expected reassuring effect of cervical length measurement in women with threatened preterm labor is lacking. Our analysis does not allow us to make statements whether this type of evaluation was done in studies of other prognostic

tests associated with preterm labor, as we did not include studies of other prognostic preterm labor medical tests, such as the fetal fibronectin test. In addition, we also did not include articles that show additional effects of the cervical length measurement in women without symptoms of preterm labor.

Although we found 70 articles that reported on studies of the accuracy of cervical length measurement in women with threatened preterm labor, we did not find any obstetrical research that documented other effects of the cervical length measurement in symptomatic women. We hope that future researchers recognize that such additional effects may be of great importance for patients as well, and that they should be assessed and quantified. For instance, patients may be reassured if they can see for themselves that the cervix is still long. In addition, this may also affect medical outcomes if cervical length measurement in itself influences potential risk factors for preterm labor, such as psychological stress [31]. For example, a short cervix may be seen in a woman who will not have a preterm delivery, but increase anxiety. Or it is possible that undesired behaviors (e.g. smoking) associated with preterm birth are reinforced by reassuring results. Until these additional effects on patient outcomes are actually measured, their existence is at best based on anecdotal evidence and the

magnitude of these effects remains unknown. Therefore, it is still unclear if such presumed additional effects have the potential to influence test recommendations about cervical length measurements.

In summary, we found that multiple authors have pointed to the potential of cervical length measurements to affect a range of patient outcomes, such as reassurance and anxiety, but these effects have not yet been measured. We suggest that such additional effects of medical testing require formal evaluation before statements about their existence are made, and that recommendations about testing and test strategies should be based on comprehensive evaluations of the effects of testing on patients. Correspondingly, future studies evaluating transvaginal cervical length measurement for preterm labor should include a more complete assessment of patient outcomes.
