ABSTRACT

Small ruminant lentiviruses isolated from peripheral blood leukocytes and target organs can be propagated in vitro in fibroblasts derived from goat synovial membrane cells. These cells are obtained from tissues collected from embryos or fetuses and are necessary for the establishment of the fibroblast primary culture. A new alternative type of host cells, derived from goat umbilical cord, was isolated and characterized phenotypically with its main purpose being to obtain cell monolayers that could be used for the diagnosis and isolation of small ruminant lentiviruses in cell culture. To accomplish this goal, cells were isolated from umbilical cords; characterized phenotypically by flow cytometry analysis; differentiate into osteogenic, chondrogenic and adipogenic lineage; and submitted to viral challenge. The proliferation of goat umbilical cord cells was fast and cell monolayers formed after 15 days. These cells exhibited morphology, immunophenotype, growth characteristics, and lineage differentiation potential similar to mesenchymal stem cells of other origins. The goat umbilical cord derived cells stained positive for vimentin and CD90, but negative for cytokeratin, CD34 and CD105 markers. Syncytia and cell lysis were observed in cell monolayers infected by CAEV-Cork and MVV-K1514, showing that the cells are permissive to small ruminant lentivirus infection in vitro. These data demonstrate the proliferative competence of cells derived from goat umbilical cords and provide a sound basis for future research to standardize this cell lineage.

Introduction

The small ruminant lentivirus (SRLV) comprises two types of viruses, the Caprine Arthritis Encephalitis virus (CAEV)

and the Maedi Visna virus (MVV); both of which are widely distributed throughout the world. CAEV and MVV share genetic similarities, molecular mechanisms of replication, morphology and similar biological interactions in their hosts. These lentiviruses cause persistent infections, including

encephalitis, arthritis, progressive pneumonia, and mastitis in goats and sheep. Like other lentiviruses, CAEV and MVV infect cells of the monocyte/macrophage lineage and dendritic cells.^{1,2}

CAEV and MVV can replicate in primary fibroblasts derived from synovial membranes or from choroid plexus cultures,^{3,4} and can also replicate in the immortalized TIGEF cell line (T Immortalized Goat Embryonic Fibroblast).⁵ These cells are obtained from the tissues collected from embryos or fetuses and are necessary for the establishment of the fibroblast primary culture.

An alternative method would involve using cells derived from goat umbilical cords, which is an invaluable tool that does not use embryos or fetuses. Generally, the umbilical cord would be discarded after calving. However, it is an excellent source material, rich in cells that are able to originate several cell types. The umbilical cord is a well-known source of mesenchymal stem cells (MSCs), which have been isolated and characterized in umbilical cord samples from canine,⁶ equine⁷ and ovine⁸ species. MSCs are a multipotent adult stem cell.⁹

Undifferentiated MSCs exhibit fibroblast-like morphology and are characterized phenotypically by the expression of surface markers; however, the characterization of these cells has not yet been fully defined. There are several positive markers described, and there is a consensus that undifferentiated MSCs should be positive for CD29, CD44, CD90, CD105, CD73 and negative for CD34, CD45, CD14 and CD3.^{10,11} MSCs are multipotent stromal cells capable of differentiating to mesenchymal lineages, including tissues such as adipose tissue, bone, cartilage and muscle.^{9,12}

The aims of the experiments in this study were to isolate, phenotypically characterize and investigate the differentiation potentials of cells from goat umbilical cords (cGUCs), with the main purpose being to obtain cell monolayers for use in the diagnosis of small ruminant lentiviruses via isolation in cell culture.

Materials and methods

Samples

All experiments were approved by the Ethics Committee for Animal Use at the State University of Ceará, protocol number 127.769.79-0. For this study, mongrel pregnant goats were used, aged between two and three years and free of infection by SRLV.

Three umbilical cord samples were collected during calving. After birth, the goat umbilical cords were clamped at both ends, i.e., next to the fetus and the goat, and then cut and packed in the transport medium. The solutions used during transport were low glucose DMEM (Dulbecco's Modified Eagle Medium) (Gibco[®], Grand Island, NY, USA), MEM-E (Minimum Essential Medium with Earle's salt and L-glutamine) (Gibco[®], Grand Island, NY, USA), PBS (phosphate buffered saline) and saline solution 0.9% (SS), supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 10% FBS. The samples were transported within 2 h to the laboratory, packed in an isothermal box with ice.

Isolation and culture of cGUCs

The tissue samples were processed in a laminar flow cabinet. The umbilical cord was washed with PBS to remove blood. The amniotic epithelium surrounding the umbilical cord was dissociated using sterile scissors and forceps. Tissue samples of umbilical cord matrix were cut into pieces of 0.5–1 cm (explants) and were plated in A25 cell culture flasks and 6-well culture plates using DMEM-low glucose or MEM-E supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 10% FBS and cultured at 37 °C in a CO₂ incubator (5% CO₂).

The cell cultures were observed in an inverted microscope every day, until proliferation of the first cells from the explants had occurred. The media was changed after 5 days to avoid any mechanical stress, and thereafter, it was replenished every third day. At 80% confluence, cells were trypsinized (0.25% Trypsin-EDTA, Gibco[®], Grand Island, NY, USA) and reseeded in new cell culture flasks.

Virus infectivity assay

The cells from the confluent monolayer after the third passage were infected with either the CAEV-Cork or MVV-K1514 strains, provided by Dr. Roberto Soares de Castro (Federal Rural University of Pernambuco – UFRPE). These strains originated from the Institut National de la Recherche Agronomique, Lyon-France. The virus infectivity assay was performed in duplicate for each of three separate experiments. The cells were incubated with viral suspension 10⁵ TCID₅₀ at a MOI of 1 for 1 h at 37 °C in a 5% CO₂ incubator. Thereafter, the supernatant was discarded and the growth medium was added (DMEM supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 2% FBS).

The cell monolayers were observed in an inverted microscope every day until the cytopathic effect caused by the virus was evident, proving that the cells were permissive for infection by SRLV.

FACS analysis

FACS analysis was performed to investigate the expression of the surface markers CD90, CD105, CD34, and the intracellular markers vimentin and cytokeratin in cGUCs after the third passage. The cells were harvested and aliquoted at a density of 10⁶ cells/mL for each marker assay. First, these cells were incubated with antibodies against surface markers [mouse anti-Human CD90 FITC, CD105 APC and CD34 APC (BD Biosciences[®], USA)] for 30 min at 4 °C in the dark. Then, the cells were permeabilized with fixation/permeabilization solution (BD Cytofix/Cytoperm Fixation/Permeabilization Kit, BD Biosciences[®], USA) for 20 min at 4 °C in the dark. Permeabilized cells were incubated with antibodies against intracellular markers [mouse anti-Human vimentin PE and cytokeratin PE (BD Biosciences[®], USA)] for 30 min at 4 °C in the dark. Thereafter, the cells were washed twice with BD perm/wash buffer (BD Biosciences[®], USA), fixed with formaldehyde buffer (PBS with 1% formaldehyde) and analyzed using a flow cytometer (FACS Calibur BD, BD Biosciences[®]). A gate was defined and

the minimum number of events constituting was set to 10,000. The negative control was processed in a similar manner but without antibodies. The data obtained was analyzed using Cell Quest Pro software and plotted as a histogram.

Adipogenic differentiation

For adipogenic differentiation, trypsinized cells (1×10^4 cells/cm 2) were seeded into a 24-well plate and incubated with DMEM supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 10% FBS. After 24 h, the medium was discarded, and the cells were incubated with StemPro® Adipogenesis Differentiation Basal Medium (Gibco®, Grand Island, NY, USA). The differentiation medium was replaced every 3–4 days. After 14 days of culture, the cells were fixed with 10% formalin at room temperature, washed with PBS, and stained with 0.5% Oil-Red O (Sigma-Aldrich®, St. Louis, MO, USA) for 15 min and Mayer's Hematoxylin (Sigma-Aldrich®, St. Louis, MO, USA) for 5 min to visualize lipid droplets.

Chondrogenic differentiation

Chondrogenic differentiation was induced in micromass cultures by seeding 5 µL droplets of cell solution (1.6×10^7 viable cells/mL) in the center of a 24-well plate. The cells were incubated with DMEM supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 10% FBS for 2 h. Afterward, the cells were fed with a specific chondrogenesis differentiation medium (StemPro®, Gibco®, Grand Island, NY, USA). The medium was replaced every 2–3 days. After 14 days, chondrogenic differentiation was confirmed by staining for Alcian Blue (Sigma-Aldrich®, St. Louis, MO, USA).

Osteogenic differentiation

To induce osteogenic differentiation, the cells from the confluent monolayer of the third passage (5×10^3 cells/cm 2) were seeded into a 24-well plate and incubated with DMEM supplemented with 300 U/mL penicillin, 300 µg/mL streptomycin, 0.5 mg/mL amphotericin and 10% FBS. After 24 h, the medium was discarded, and cells were cultured in StemPro® Osteocyte Differentiation Basal Medium (StemPro®, Gibco®, Grand Island, NY, USA). The medium was replaced every 2–3 days. After 14 days of culture, the osteogenic differentiation of stem cells was confirmed by Alizarin Red S staining (Sigma-Aldrich®, St. Louis, MO, USA).

Results

Growth and culture characteristics

Goat umbilical cord cells started to migrate out of explants after 3–6 days of culture, and the cells gradually grew into small colonies. In the samples transported in DMEM and MEM-E, cell proliferation started 3 days after beginning the incubation, whereas samples transported in PBS started proliferating after 5 days and the samples packed in SS after 6 days. These data demonstrated that DMEM and MEM-E enable

better preservation of the samples and, consequently, enable better acquisition of cells.

During the initial days of incubation, cells displayed a non-fibroblastic, rounded, epithelial cell-like phenotype (Fig. 1A). Later, cells attained a typical fibroblast-like spindle-shaped structure (Fig. 1B). As growth continued, adjacent colonies interconnected with each other, and a confluent monolayer was obtained (Fig. 1C). Cell monolayers derived from goat umbilical cords were used in viral challenge assays, for immunotyping by flow cytometry, and in mesodermal lineage differentiation assays.

The growth media used in this study (DMEM or MEM-E supplemented with 10% FBS) were highly suitable to sustaining the cells, resulting in high rates of growth and expansion of the cell stock. After 15 days, cells had grown to 80% confluence, at which time the first passage was performed. In later passages, cultured cells reached 80–90% confluence faster, in approximately 3–4 days.

Cytopathicity of SRLV in cGUCs

The cGUCs are highly permissive to SRLV infection in vitro. The cytopathic effects appeared 7 days after inoculation. Classical giant multinucleated cells (syncytia) were observed in the monolayers infected with CAEV-Cork virus (Fig. 2B). The cells infected with MVV-K1514 virus underwent syncytia formation and cell lysis. The cytopathic effects progressed, resulting in the progressive destruction of the cell monolayer (Fig. 2A). The negative control for the viral infectivity assay is shown in Fig. 2C.

Immunophenotypic characterization by flow cytometry

In vitro cultured, third-passage cGUCs were analyzed by FACS. FACS analysis revealed that these cells were positive for the expression of vimentin (91.6%) and CD90 (23%) but were negative when staining for CD105 (3.66%), CD34 (2.95%) and cytokeratin (1.67%) (Fig. 3).

Mesodermal lineage differentiation

Adipogenic differentiation of cGUCs was confirmed by Oil Red-O staining. After incubating these cells with adipogenic-inducing medium for 14 days, small lipid droplets were present in the cytoplasm (Fig. 4A).

The chondrogenic potential of cGUCs was evaluated by in vitro micromass culture of these cells in a specific differentiation medium. After 14 days of incubation, the accumulation of sulfated proteoglycans was visualized by Alcian Blue staining (Fig. 4B).

In the osteogenic differentiation assay, the cells proliferated and reached complete confluence after 8–10 days of incubation with differentiation medium. The cellular aggregates were then observed and were characterized by calcium deposits, which were demonstrated by positive Alizarin Red staining (Fig. 4C).

Discussion

The umbilical cord is composed of several different components (amniotic membrane, umbilical cord matrix, umbilical cord vein, and umbilical cord blood) that can be used as sources of MSCs.⁶ In this study, cGUCs were isolated from the umbilical cord matrix and were cultured in DMEM or MEM supplemented with 10% FBS. These conditions were found to be very well suited for the maintenance of the cultured cells, and contributed to quick amplification of the cell stock. Several culture media have been tested for the maintenance of MSCs, such as MEM, DMEM, RPMI-1640 and Basal Medium Eagle (BME), supplemented with FBS, generally at a concentration of 10–20%. The choice of the culture medium is important for the successful growth of MSCs during *in vitro* cell culture.¹³

During the initial days of incubation, the population of cells was heterogeneous, including both epithelial-like and fibroblast-like cells. However, after passaging, the epithelioid cell population disappeared from the culture and most of the cells exhibited a fibroblast-like appearance. These data are consistent with the observations of Pratheesh et al.¹⁴ who observed similar morphological features in caprine mesenchymal stem cells derived from amniotic fluid (cAF-MSCs) and also with Ren et al.¹⁵ in their study with goat adipose-derived stem cells (ADSCs). In addition, the fibroblast-like cells derived from goat umbilical cord matrix are similar to MSCs in their general features.

The aim of the present study was to investigate the capacity of cells from goat umbilical cord matrix to generate cell monolayers that could be used for viral diagnosis in cell culture assays. It was demonstrated that these cells are highly permissive to SRLV infection *in vitro*. Syncytia and cell lysis were observed after 7 days of inoculation with the CAEV-Cork strain, and similar results were observed with the MVV-K1514 strain. These results resemble the effects observed after infection of synovial membrane cells, which are the cells traditionally used for this purpose.

High amounts of small ruminant lentivirus can be produced *in vitro* using fibro-epithelial synovial membrane cells or choroid plexus cells from goats or sheep.^{16,17} However, the disadvantage is that these types of cells can only be obtained from embryos or fetuses, whereas goat umbilical cords offer a great alternative for the generation of fibroblasts because the umbilical cord would be discarded after calving and thus represents a highly convenient source material for generation of cells.

Other cell types permissive for small ruminant lentivirus infection are microglia¹⁸; dendritic cells²; epithelial cells from the lung¹⁹; mammary gland²⁰; third eye lid²¹; kidney²²; uterus and epididymis^{23,24} and endothelium; smooth myocytes^{19,25}; granulosa cells²⁶; and parenchyma cells from the liver and heart.²⁷

The phenotypic characterization of cGUCs was performed by flow cytometry. The general strategy for identifying *in vitro* cultivated mesenchymal stem cells was executed as per the ISCT recommendation (International Society for Cytotherapy),

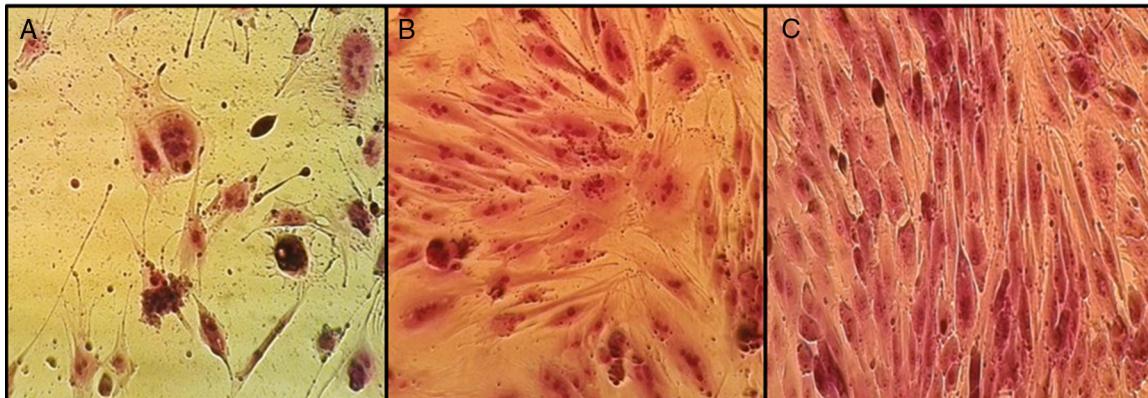

Fig. 2 – Cytopathic effects caused by MVV and CAEV. (A) Cell lysis and syncytia caused by MVV. (B) Giant multinucleated cells caused by CAEV. (C) Negative control for the viral infectivity assay.

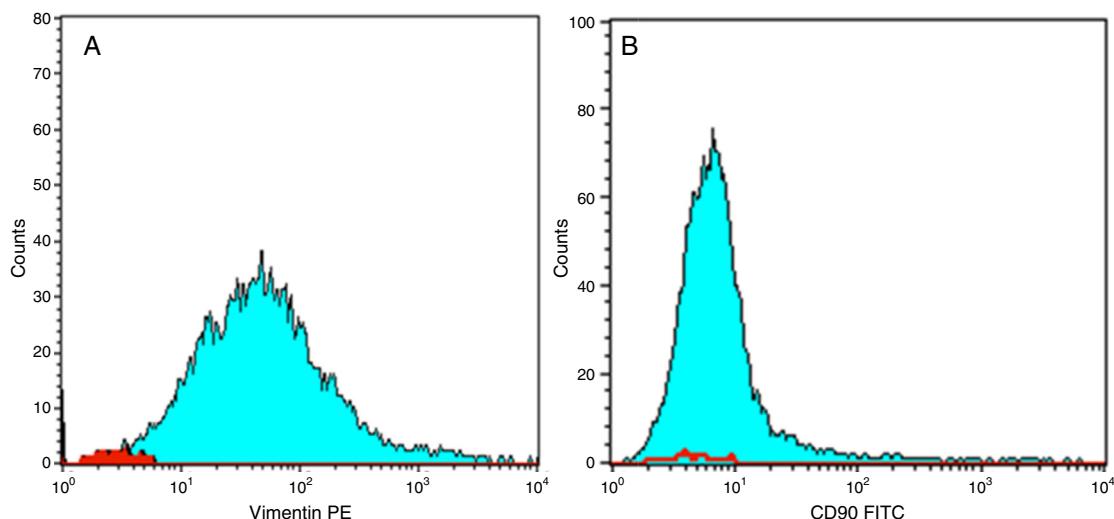

Fig. 3 – FACS analysis of Vimentin and CD90, *in vitro* culture, third passage cGUCs. (A) Vimentin PE. (B) CD90 FITC. Calibrated histogram representing the number of events on the Y-axis and fluorescent intensity on the X-axis. The red area histogram indicate negative control.

which is to analyze the expression of cell-surface markers such as CD-73, CD-44, CD-90 and CD-105.^{28–31} It was demonstrated that the cGUCs are positive for vimentin and CD90, whereas they were negative for cytokeratin, CD105 and CD34. These results can be compared with those of other studies. Ren et al.¹⁵ described MSCs from goat adipose that stained positively for vimentin, CD49d and CD13 and negatively for CD34 and CD106. Caprine mesenchymal stem cells derived from amniotic fluid were positive for CD90, CD105, CD73, and negative for CD34.¹⁴

Vimentin is present in normal and pathological mesenchymal tissues and is an important marker of the mesoderm. Positive vimentin staining verified that the cGUCs were derived from mesodermal stem cells.³² Cytokeratin-negative staining demonstrated the predominance of fibroblast-like cells and is consistent with the observation that the epithelial-like cells disappeared from culture and could no longer be found from third passage onward. Additionally, most of the cells exhibited a fibroblast-like appearance. CD34 is a surface marker of hematopoietic stem cells (HSCs) and is expressed in lymph nodes, bone marrow HSCs, and various endothelial

cells. CD34-negative staining demonstrated that cGUCs were not derived from circulating stem cells.^{9,33}

The cGUCs from umbilical cord matrix are negative for CD105. This marker is usually expressed in mesenchymal stem cells; however, there is not yet a definitive marker for MSCs. There are a large number of positive markers described, but each group of investigators uses different markers, none of which are specific or used singly. Perhaps the differences between studies may be attributed to variations in culture methods or the stage of cell differentiation.³⁴

In this study, FACS analysis revealed low levels of CD90 marker expression (23%) in comparison to Vimentin (91.6%). CD90 is known to be a negative regulator of hematopoietic proliferation.³⁵ Its expression, in association with CD34-negative staining, confirms that there was no evidence of hematopoietic precursors in this culture. The expression levels of surface markers are also different in other studies. Chang et al.³⁶ isolated cells from umbilical cord blood (UCB) and observed the following two different morphologic phenotypes: flattened fibroblastic clones and spindle-shaped fibroblastic clones. CD90 was expressed

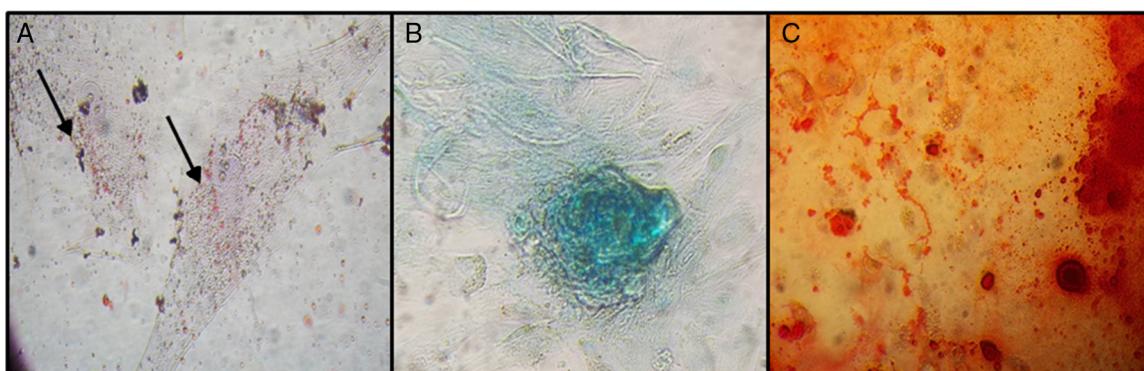

Fig. 4 – Mesodermal lineage differentiation. Adipogenic differentiation (A). Chondrogenic differentiation (B). Osteogenic differentiation (C).

differently by these two cell populations. Spindle-shaped, clonogenic MPCs expressed a high level of CD90, while flattened, clonogenic MSCs did not express CD90. These data might explain the inconsistent results regarding CD90 expression in UCB-derived MSCs in various reports.^{37–39}

The differentiation potential of cGUCs was investigated. These cells showed a capacity to differentiate into adipocytes, chondrocytes or osteoblasts when incubated with the appropriate differentiation medium. Pratheesh et al.¹⁴ demonstrated that MSCs from goat amniotic fluid, such as their marrow counterparts, were able to differentiate into adipose cells in addition to differentiating into osteogenic and chondrogenic lineages. Goat adipose-derived stem cells showed the same differentiation potential.¹⁵ Goat-derived multipotent MSCs have been established from bone marrow and successfully induced to differentiate into osteogenic and adipogenic lineages under specific culture conditions.⁴⁰

The present study establishes that goat umbilical cord cells are permissive for small ruminant lentivirus infection *in vitro*, can be successfully used in cell culture diagnosis, and represent a new alternative source of host cells for virus isolation. These cells exhibit a fibroblast morphology, and immunophenotype, growth characteristics and mesodermal lineage differentiation potential that are all similar to MSCs. These cGUCs also express vimentin and CD90 but are negative for CD34. These data demonstrate the proliferative capacity of cells from goat umbilical cords, and they establish a sound basis for future research aimed at standardizing the cell lineage and using these cells for the diagnosis of several diseases.
