Abstract

We combined *de novo* mutation (DNM) data from 10,927 cases of developmental delay and autism to identify 253 candidate neurodevelopmental disease genes with an excess of missense and/or likely gene-disruptive mutations. Of these genes, 124 reach exome-wide significance ($p < 5 \times 10^{-7}$) for DNM. Intersecting these results with copy number variation morbidity data shows an enrichment for genomic disorder regions (30/253, LR+ 1.85, $p = 0.0017$). We identify genes with an excess of missense DNMs overlapping deletion syndromes (e.g., *KIF1A* and the 2q37 deletion) as well as duplication syndromes, such as recurrent *MAPK3* missense mutations within the

INTRODUCTION

The importance of *de novo* mutations (DNMs) underlying neurodevelopmental disorders (NDDs) has been recognized for many years. Some of the strongest genome-wide evidence came from early copy number variation (CNV) studies, which consistently showed an excess of *de novo* as well as large private CNVs in patients with autism, developmental delay (DD) and epilepsy¹⁻⁴. Significance based on CNV recurrence was more readily achieved from smaller sample sizes because of elevated mutation rates in regions flanked by segmental duplications⁵ or hotspots of recurrent rearrangement near telomeres⁶. In many cases the individual genes underlying the genomic disorders remain unknown.

The advent of next-generation sequencing and exome sequencing rapidly accelerated our ability to specify genes associated with potentially pathogenic *de novo* single-nucleotide variants (SNVs) for both DD and autism^{7,8}, although recurrent mutations occurred more rarely^{9,10}. Different statistical models for discovery of genes based on recurrent SNV mutation have been developed, including those based on chimpanzee-human divergence¹¹, trinucleotide mutation context¹², and clustering of DNMs¹³⁻¹⁵. Despite extensive CNV analyses of nearly 45,000 patients with autism and DD¹⁶⁻¹⁸, few attempts have been made^{18,19} to integrate the wealth of CNV data with recent exome sequencing results despite a common mutational model of dosage imbalance.

In this study, we perform an integrated meta-analysis combining DNM exome sequence data from individuals with autism spectrum disorder (ASD), intellectual disability (ID) and/or DD²⁰ with CNV morbidity data. Because of the significant comorbidity between ID and ASD^{21,22} and the fact that autism cases with a severe DNM are enriched in DD²³, we

overlay these data with known genomic disorders. The goals of this study are threefold: 1) provide an integrated list of candidate NDD genes based on multiple lines of DNM and CNV evidence, 2) compare different models of recurrent mutation, and 3) identify the most likely genes underlying pathogenic microdeletion and microduplication CNVs associated with DD.

RESULTS

Genes enriched for *de novo* SNV mutation and model comparisons:

We compile *de novo* variation identified from exome sequencing of 10,927 cases with NDDs from the denovo-db v.1.5 database release²⁰. This includes 5,624 cases with a primary diagnosis of ASD and 5,303 cases with a diagnosis of ID/DD collected from 17 studies^{11,23-38} (Supplementary Table 1). We consider all protein-altering and likely gene-disruptive (LGD) mutations, including frameshifts, splice donor/acceptor mutations, start losses and stop gains. The combined set of 12,172 DNMs includes 2,357 LGD and 9,815 missense mutations.

We initially applied two statistical models. The first incorporates locus-specific transition/transversion/indel rates and chimpanzee-human coding sequence divergence¹¹ to estimate the number of expected DNMs, hereafter referred to as the chimpanzee-human divergence model or the CH model. The second model, denovolyzeR¹², estimates mutation rates based using trinucleotide context and incorporates exome depth and divergence adjustments based on macaque-human comparisons over a ± 1 Mbp window and accommodates known mutational biases, such as CpG hotspots. Both models apply their underlying mutation rate estimates to generate prior probabilities for observing a specific number and class of mutations for a given gene. While both models incorporate LGD and missense probabilities, we recently modified the CH model to incorporate CADD scores^{39,40} allowing us to also specifically test for enrichment for the missense subset of the predicted most severe 0.1% of mutations (i.e., CADD scores over 30 or MIS30). Such missense mutations are more likely to be functionally equivalent to an LGD mutation and have been shown to be significantly enriched in NDD cases compared to controls¹⁴. To account for the sensitivity biases, we applied an upper bound baseline mutation rate assumption of 1.8 DNMs (derived from high-coverage genome sequencing data) to the CH model, which exceeds the overall DNM rate of this cohort.

Combined, the two models (union set) identify 253 candidate NDD genes with evidence of excess DNM at a false discovery rate (FDR) $< 5\%$ and at least two mutations for at least one mutational category (Table 1, Table 2). This includes 145 genes with excess LGD mutations and 123 genes with excess missense mutations. Among these, 29 genes demonstrate evidence of both LGD and missense mutations (Figure 1, Table 1, and Supplementary Table 2). In general, both models highlight similar genes (Figure 1, Supplementary Note), particularly for LGD events where 73.1% (106/145) of genes are shared. This stands in contrast to recurrent missense DNMs where only 51.2% (63/123) of the genes overlap between the models suggesting that additional model refinement is required to more accurately predict pathogenic missense mutations. A more stringent application of the

exome-wide Bonferroni family-wise error rate (FWER) identifies a union of 124 genes (Supplementary Table 2, Supplementary Note).

We identified additional evidence of disease association, from a comprehensive database and PubMed literature search, for 204/253 genes (Methods) indicating that 49/253 union genes (10/124 FWER union genes) presented here are novel associations (Supplementary Table 2, Supplementary Table 3). Of these novel genes, 61% (30/49) demonstrate DNM in both ASD and ID/DD patients. We wish to note that neither FDR nor FWER, however, are metrics of pathogenicity but rather simply thresholds of significance to identify genes for further investigation.

Since it has been well established that NDD genes are less tolerant to mutation, we categorize the 253 genes into different functional groups and compare their tolerance to mutation in the general population using three metrics: residual variance to intolerance score (RVIS); probability of loss-of-function intolerance (pLI); and missense constraint scores (missense Z scores). For both pLI and missense Z scores, we utilized the ExAC subset with known neuropsychiatric cohorts removed (45,376 individuals)⁴¹. For genes with an enrichment of LGD variants, we observe a significant increase in pLI scores compared to all other genes ($p = 8.3 \times 10^{-58}$ two-tailed Wilcoxon rank-sum test, ROC AUC = 0.90) (Figure 1E). We also observe a significant increase in missense constraint (missense Z scores) among genes with enrichment for missense variation ($p = 1.9 \times 10^{-44}$ two-tailed Wilcoxon rank-sum test, ROC AUC = 0.87) (Figure 1F). Similarly, we observe a significant RVIS depletion for all categories where at least two genes were identified (Figure 1G).

Examination of a combination of constraint metrics is particularly valuable as a small number of genes demonstrate conflicting results, such as the LGD- and missense-enriched gene *MEF2C*, which is involved in severe ID when disrupted by deletions or mutations⁴² and demonstrates constraint by RVIS, but not by pLI (RVIS = 18.97, pLI = 2.4×10^{-3} , missense Z score = 4.47). Interestingly, among genes without pLI or RVIS support, we identified established ASD/ID genes in addition to the expected potential false positives. Among the union genes 82.6% (209/253) have no detected LGD or missense DNM in controls (n = 2,278 controls; Supplementary Note). The detection of control events may represent incomplete penetrance, variable expressivity, undiagnosed/subclinical controls, or benign variation (primarily in the case of missense variation). None of the recurrent control DNM genes reach exome-wide FDR significance. While some of these are plausible candidates, disease significance should be considered with caution until additional functional and clinical data establish their role.

ASD versus ID/DD genes:

We investigated the distribution of LGD and missense mutations between the ASD and ID/DD cohorts. The majority of this NDD gene set (68.4% (173/253) of the union and 72.3% (107/148) of the intersection) show evidence of DNM in both ASD and ID/DD cohorts, highlighting the utility of joint analyses. Although a small number of genes are specific or enriched for a diagnosis of ID/DD ($q < 0.01$, one-tailed Fisher's exact test), none are yet statistically enriched for ASD (Supplementary Figure 1). A few genes (*WDFY3*, *DSCAM* and *CHD8*) trend toward ASD diagnosis. To eliminate potential ascertainment bias

in discovery, we repeated the overlap analysis considering gene discovery independently in each cohort (Supplementary Note). Considering all 253 genes and the full set of NDD patients, we calculate that 17.7% (1,932/10,927) of the samples have at least one *de novo* event in this gene set.

The proportion of patients with a DNM is significantly higher for ID/DD (26.8% or 1,421/5,303 patients) when compared to ASD (9.1% or 511/5,624 patients) (OR = 3.66, $p = 1.62 \times 10^{-133}$, two-tailed Fisher's exact test). While this may be partially biased by the differences in DNM sensitivity between exome studies, this observation exceeds the baseline 1.58-fold excess of LGD DNM in ID/DD cohorts and thus reflects differences in heterogeneity between the disorders. Further supporting this bias of LGD events to ID/DD, Simons Simplex Collection (SSC) autism probands who carried an LGD DNM in one of the LGD genes were less likely to be high-functioning. Instead, there was an overrepresentation of ID (< 70 IQ, expected 753/2,445, observed 42/95) and low-to-normal IQ ranges ($70 < IQ < 100$, expected 1,018/2,445, observed 45/95) compared to the high IQ probands (> 100 IQ, expected 674/2,445, observed 8/95) ($p = 4.0 \times 10^{-5}$, two-tailed likelihood ratio test) (Supplementary Table 4). Among the autism mutation carriers, we observe a nominal enrichment for increased severity of repetitive behavior (RBS-R [$t(18) = 3.12$, corrected $p = 0.048$], two-tailed independent samples t-test) but were overall underpowered to further disentangle associated phenotypic features.

Network enrichment and patterns of brain expression:

Examination of the 253 genes identified by the union of both statistical approaches suggests that our set is strongly enriched for functionally related networks of genes. The STRING database, for example, identifies a highly significant 1.8-fold (1,067 edges vs. 573 expected) enrichment in interactions among the 253 union genes ($p < 1.0 \times 10^{-16}$, one-tailed hypergeometric test). Given this high level of interconnectivity, we applied MAGI⁴³, a gene network discovery tool, to identify potential gene clusters, functional enrichments, and additional candidate interactions and highlight the top four protein-protein interaction (PPI) and co-expression networks (each at $p < 0.01$, one-tailed permutation test) and their associated PANTHER functional enrichments (Figure 2A-D, Supplementary Tables 5-7).

Module 1 (20 genes) delineates “regulation of transcription from RNA polymerase II promoter” ($p = 0.0269$, one-tailed Bonferroni adjusted binomial test) (Figure 2A, Supplementary Tables 5-7) and contains 15 significant genes in addition to three candidates that do not yet reach significance (*CREB1*, *RBBP5*, *CBX5*) and two genes (*SREK1*, *SMARCB1*) with no DNM in our current data set. Module 2 highlights multiple functions relating to neurotransmitter signaling ($p = 0.0358$; one-tailed Bonferroni adjusted binomial test) and synaptic signaling ($p = 8.91 \times 10^{-5}$, one-tailed Bonferroni adjusted binomial test) (Figure 2B, Supplementary Tables 5-7) and contains nine significant genes in addition to ten genes that do not reach significance (*DLG2*, *HTT*, *AP2A2*, *AP2M1*, *KCNJ4*, *KCNB1*, *STX1A*, *GRIN2A*, *GRIN1*, *CAMK2A*) and one gene with no DNM (*PRKCB*). Module 3 highlights the “transmembrane receptor protein serine/threonine kinase signaling pathway” ($p = 0.002$; one-tailed Bonferroni adjusted binomial test) (Figure 2C, Supplementary Tables 5-7) and contains eight significant genes in addition to 21 genes that do not reach

significance (*SMURF2*, *SMURF1*, *CDC73*, *RNPS1*, *RBBP4*, *UBE3A*, *CUL1*, *CHMP1A*, *FBXW11*, *VCP*, *VPS4A*, *PPP5C*, *PRPF38A*, *SKIL*, *HSPA4*, *PSMD3*, *UIMC1*, *GAPVD1*, *NLGN2*, *GTF3C1*, *NRXN1*) and six genes with no DNM (*ING2*, *SRSF4*, *FAF1*, *UBC*, *HSP90AB1*, *YWHAB*). Finally, Module 4 highlights c-Jun N-terminal kinase (JNK) ($p = 4.65 \times 10^{-5}$, one-tailed Bonferroni adjusted binomial test) and mitogen-activated protein kinase (MAPK) ($p = 3.13 \times 10^{-6}$, one-tailed Bonferroni adjusted binomial test) cascades (Figure 2D, Supplementary Tables 5-7) and contains two significant genes in addition to 15 genes that do not reach significance (*RPS6KA3*, *RASGRF1*, *MAPK8IP1*, *SMAD3*, *DUSP3*, *MAPK9*, *SPTBN1*, *ACTN4*, *CAMK2G*, *TFE3*, *PRKARIA*, *SNAP25*, *MAPK8IP2*, *MAPK8IP3*, *PRKAR1B*) and three genes with no DNM (*SYN1*, *MAPK1*, *PRKACA*). Among these nonsignificant genes are many previously identified NDD candidate genes (e.g., *NRXN1*, *GRIN2A*, *CAMK2A*)⁴⁴⁻⁴⁶ suggesting this group as a potential target for future screening and disease gene discovery.

In addition to enrichment in the PPI context, we also note functional cell-specific and tissue-specific enrichment analyses (CSEA and TSEA)^{47,48} obtained primarily from mouse expression data sets. As expected, the 253 gene set is enriched for the brain expression with a bias toward early to mid-fetal gene expression in the cortex, striatum and amygdala (Figure 2E). Among these, the greatest specificity is observed for early to early mid-fetal cortical development. By CSEA, the *de novo* gene set shows enrichment in both classes of medium spiny neurons within the striatum (striatum D1+ and D2+ medium spiny neurons Benjamini-Hochberg (BH)-corrected $p = 0.013$ and $p = 0.011$, one-tailed Fisher's exact test) at a pSI (specificity index p-value) threshold of 0.05. Additionally, we observe nominal significance for D1+ and D2+ spiny neurons (uncorrected $p = 0.027$ and $p = 0.023$, one-tailed Fisher's exact test) at a pSI of 0.01 (Supplementary Figure 2A), and through a further analysis of available single-cell sequencing data, two pyramidal neuron subtypes (S1PyrL5, BH $p = 0.008$; one-tailed Fisher's exact test) and the hippocampus (CA1Pyr1, BH $p = 0.046$; one-tailed Fisher's exact test) (Supplementary Figure 2B, Supplementary Note).

As a final analysis, we also assess the expression patterns of the union gene set using human RNA-seq data sets. The gene set, irrespective of class of mutation, is significantly enriched for a pan-neuronal pattern of expression when compared to control sets selected based on synonymous DNM in cases and genes with recurrent DNM in controls samples (Figure 3, Supplementary Figure 3). This analysis does not highlight specific cell types when compared to control genes ($p = 0.52$, two-tailed corrected Wilcoxon rank-sum test) but does show slightly higher expression across neuronal cell types ($p = 0.0001$; two-tailed corrected Wilcoxon rank-sum test) even after controlling for gene length (Supplementary Figure 3). The 253 union gene set shows a strikingly broad expression profile across adult human cortical neuron types, including GABAergic (inhibitory) and glutamatergic (excitatory) neurons, compared to control genes (Figure 3A, Supplementary Figure 3, Supplementary Note).

Projected rates of gene discovery:

Based on the number of genes that reach significance for DNM in our cohort of 10,927 cases, we estimate the potential yield by mutational class and the CH model. To this end, we

subsampled smaller populations from our set 10,000 times each and tested for how many genes would reach significance using the CH model in a resampled cohort. We assess logistic growth models for each mutation class and select the best fitting model by Bayesian information criteria (BIC) to predict future performance. For genes with excess LGD DNMs, we observe what appears to be a rapid upcoming plateau in gene discovery with an asymptote at 216 genes (95% CI 208-225) (BIC linear model - asymptotic regression model = 259) (Figure 4). Similarly, for genes with an excess of MIS30 DNMs, the model predicts an asymptote of only 65 genes (95% CI 63-67) (BIC linear model - Weibull model = 250) (Figure 4). By contrast, genes with an excess of recurrent missense mutations cannot yet be projected (Supplementary Note).

CNV intersection:

In order to identify potentially dosage-sensitive genes underlying pathogenic CNVs, we intersect the 253 candidate gene set with a list of 58 genomic disorders based on previous CNV morbidity maps and the DECIPHER database (Table 3, Supplementary Table 2, Figure 5). Considering all genes with a *de novo* variant (n = 6,886), we find that 30 of 253 significant genes intersect a genomic disorder region, compared to 426 of 6,633 non-significant genes intersecting a disorder. This represents a significant (p = 0.0017, two-tailed Fisher's exact test) enrichment (LR+ 1.85 [95% CI 1.38 - 2.43]) compared to expectations supporting the notion that neurodevelopmental CNVs and DNMs converge on a common genetic etiology of gene-dosage imbalance. While we are underpowered to detect enrichment for any specific mutational and CNV class interactions by post-hoc testing, as expected LGD-significant genes and deletion disorders demonstrated the strongest enrichment among the four combinations (p = 0.1, two-tailed Fisher's exact test, LR+ = 1.77 [95% CI 1.2 - 2.54]). Given the known complexity of gene regulation in CNVs⁴⁹, we highlight candidates representing all interaction types (Table 3, Supplementary Table 2) with the expectation that the strongest candidates will correspond to a simple model of haploinsufficiency.

Many genomic disorders intersect with a single DNM-enriched gene, confirming a known CNV gene association, including *KANSL1* (Koolen-de Vries)⁵⁰, *SHANK3* (Phelan-McDermid)⁵¹, *RAI1* (Smith-Magenis)⁵², *NSD1* (Sotos)⁵³, *WHSC1* (Wolf-Hirschhorn)⁵⁴, *BCL11A* (2p15-16.1 microdeletion)⁵⁵, *EHMT1* (9q34 deletions / Kleefstra syndrome)⁵⁶, and *CREBBP* (Rubinstein-Taybi)⁵⁷ (Table 3, Supplementary Table 2). In addition, this analysis also highlights genes that have been implicated as candidates by case reports, functional studies, or smaller CNVs (Table 3, Supplementary Table 2). Among these, we identify an excess of recurrent missense mutation in *MAPK3* mapping to the 16p11.2 microdeletion/microduplication region associated with ASD and ID⁵⁸. Recurrent LGD mutations in *PHF21A*, a gene previously implicated by translocations and focal CNVs^{59,60}, map to the Potocki-Shaffer deletion region, while an excess of missense mutations in *KIF1A* correspond to the 2q37 deletion syndrome region^{61,62}. Recurrent LGD DNMs in *SIN3A*, a REST and MECP2 interactor, map to the 15q24 deletion region⁶³⁻⁶⁵. *PPM1D* has been linked to ID⁶⁶ and is located in the 17q23.1q23.2 deletion region. *CLTC* has been linked to multiple malformations and DD and is located in the 17q23 deletion region⁶⁷. Genes

enriched for recurrent missense DNM, *YWHAG* and *GABRB3*, co-localize to the Williams-Beuren distal and Prader-Willi deletion/duplication regions, respectively⁶⁸⁻⁷⁰.

Finally, we also consider as part of this analysis the 14 regions identified as significant for CNV burden¹⁸ and identify five candidate intersections (Table 3). These include *SATB2* in the 2q33.1 region^{18,71}; *MEF2C*, which demonstrated focal deletions, functions at cortical synapses and has been independently linked to hyperkinesia and epilepsy^{72,73}; *CHD4* in the 12p13 duplication region, which has been linked by both a genome-wide association study (GWAS) and DNM to an ID syndrome^{74,75}; and *WDFY4* in the 10q11.23 duplication region, which appears to be a novel finding at this time.

A second category of CNVs are those that intersect more than a single gene (Table 3, Supplementary Table 2). The 2q33.1 region contains several potentially high-impact candidates, including *HECW2*, which has been linked to neurodevelopmental delay, ID and epilepsy by missense mutations^{27,76}; *SATB2*, which has been independently identified by focal CNVs^{18,71}; *ABI2*, which is a candidate for autosomal recessive ID⁷⁷; and *SF3B1*, which interacts directly with the ID gene *PQBPI*⁷⁸. Similarly, in the 2p15-p16.1 deletion region we identify both the primary gene *BCL11A*⁵⁵ as well as a second candidate gene in the minimal critical region, *PAPOLG*⁷⁹, which is enriched for severe missense DNM. Finally, in the 2q11.2q13 deletion region we identify both *POU3F3*, which has been linked to ID and dysmorphic features by focal deletions⁸⁰, and *RFX8*, which has limited functional information in the literature.

DISCUSSION

Exome sequencing of parent-child trios is a particularly powerful tool for the identification of genes, which when disrupted lead to pediatric NDD. The use of two DNM models, CH model and denovolyzeR, identifies a high-confidence intersection (n = 148 genes) and a comprehensive union set (253 genes), which reach significance by one or both models. An advantage of using both is that we identify high-risk candidate genes unique to each model (n = 75 additional genes), including several where DNMs have already been associated with neurodevelopmental disease. Examination of this gene set in the context of general population (i.e., ExAC) confirms that this set list is enriched for genes that are constrained in the general population (LGD pLI p = 8.3×10^{-58} , missense Z score p = 1.9×10^{-44} , two-tailed Wilcoxon rank-sum test, RVIS p < 1×10^{-7} to 2.0×10^{-2} , Bonferroni adjusted Tukey HSD test) (Figure 1).

While intolerance metrics are useful to enrich for pathogenic genes, our analysis suggests caution in strict application of a specific cutoff or even a single metric. Several known pathogenic genes are borderline by only one intolerance score, while several are poorly constrained by both metrics (e.g., *MECP2* and Rett syndrome; RVIS = 32.4, pLI = 0.66). For example, we identify 20 genes that are intolerant to mutation by pLI but not RVIS (RVIS > 20). Some of these are well-established genes (e.g., *KANSL1* and the Koolen-de Vries syndrome)⁵⁰ and the basis for this discrepancy is unknown but may relate to the fact that part of the gene is duplicated complicating genome-wide analyses of intolerance. Among targets poorly constrained by both metrics, the Bohring-Opitz syndrome gene, *ASXL1*, was

recently highlighted for the presence of somatic mosaic variants in the ExAC population (from which both the RVIS and pLI score are derived)⁸¹.

Our projection estimates indicate that gene discovery based on recurrent LGD or severe missense mutations (MIS30) will soon plateau (Figure 3). Clinical interpretation of patients with the only DNM in a previously unobserved gene will remain a challenge. Partitioning patients based on additional phenotypic criteria, sub-selecting genes based on functional pathway enrichment⁴³, integration of inherited variation (e.g., TADA)⁸², or targeting a small number of genes in much larger cohorts^{10,11} are all potential strategies for associating specific genes with a phenotype under these conditions. For example, analysis of this set of DNMs in the context of MAGI modules further identified key functional categories, including neurotransmitter/synaptic signaling and JNK/MAPK cascades. This analysis identifies 46 genes with DNMs among the four modules that do not yet reach significance but likely represent functionally important targets for future screens.

In contrast to LGD and MIS30 DNM, the number of genes that will be identified by missense DNM generally has not yet begun to approach an asymptote. Sample sizes are just now beginning to reach the level where signatures of recurrence and missense clustering are being detected for a relatively modest number of genes—most of which are only nominally significant^{14,15}. We propose that this class of mutation (less severe or clustered missense DNMs) represents the most promising reservoir for future gene discovery but will require much larger whole-exome and whole-genome data sets to tease apart. As the number of exomes grows for both ASD and DD, the maintenance and curation of *de novo* databases will be especially important in this regard²⁰.

Previous studies have implicated larger CNVs and increased mutation burden with more severe phenotypic outcomes and here we observe that the majority of DNM in the 253 genes originates from ID/DD cases (>3:1, Supplementary Table 8). Importantly, DNM-enriched genes significantly overlap known pathogenic CNV regions ($p = 0.0017$, two-tailed Fisher's exact test, LR+ 1.85 [95% CI 1.38 - 2.43]) supporting a common genetic etiology. These specific targets have offered both independent confirmation of existing single-gene associations (e.g., *KANSL1* in the 17q21.31 region), additional support for candidate genes (*MAPK3* in the 16p11.2 region), and further support for potentially oligogenic effects with multiple compelling candidate genes (*HECW2*, *SATB2*, *ABI2*, and *SF3B1* in the 2q33.1 deletion region). This is consistent with findings suggesting a role for multiple hits in ASD^{83,84}. Among the genes with recurrent mutation and CNV intersection, *MAPK3* is particularly interesting with respect to the chromosome 16p11.2 microduplication. Several functional studies on 16p11.2 deletion and duplication mice as well as *Drosophila* models have suggested that *MAPK3* is a key regulator of the syndrome: being downstream of other ASD target genes; involved in axon targeting and regulation of cortical cytoarchitecture; and being the most topologically important gene in the region by PPIs⁸⁵⁻⁸⁷. Our analysis builds on these studies by providing evidence of recurrent missense mutation enrichment in human NDDs.

Finally, it is interesting that the 253 genes we highlight in this meta-analysis demonstrate a pan-neuronal expression pattern with the majority of genes being expressed in all

GABAergic (inhibitory) and glutamatergic (excitatory) neuron types (Figure 3), suggesting these genes have the potential to alter many paths in the adult cortical circuit. While the majority of genes are broadly expressed across neuronal cell types, a subset demonstrates evidence of specific expression. More specifically, we observed enrichment for genes specifically expressed in the D1+ (19 genes) and D2+ (18 genes) medium spiny neurons of the striatum (13 genes are shared in the D1+ and D2+ lists) in mouse brain (Supplementary Figure 2A). Previously, Dougherty and colleagues highlighted this particular brain region based on a survey of genes reported as autism candidate risk genes⁴⁸. Using a CSEA, we now extend this observation to NDD genes enriched for recurrent DNM. Remarkably, a similar enrichment was recently reported in autistic individuals with multiple DNMs in coding and putative noncoding regulatory DNA⁸⁴. We also observe a similar signature for genes where nominal significance has been observed for clustered DNMs. While many of the genes enriched for D1+ and D2+ expression are not exclusive to the striatum and are more broadly expressed (as demonstrated by the enrichment signal at the lowest specificity threshold), the striatum has been implicated in ID and autism pathology by numerous studies⁸⁸⁻⁹⁷. The striatum is particularly compelling as it has been linked to repetitive behaviors⁸⁸ core to the autism phenotype and also to genes known to be involved in DD, including *CHD8*, *SHANK3*, *FOXP2*, and *KCNA4*^{89,90,93,96,97}. While the striatum is most strongly linked to autism core phenotypes, our observation of enrichment in a more general DD cohort suggests that, while the general bias of cortex genes to ID and striatum genes to ASD⁹² still holds, the diverse expression patterns of genes across the brain at complex developmental time points may have substantial functional overlap among subtypes of NDDs that will require deep phenotyping and imaging to tease apart.

In conclusion, the 253 genes that show evidence for recurrent DNM represent a starting point for further functional and phenotypic investigations. Of these genes, 124 reach a strict GWAS threshold of significance strongly arguing that DNM in these genes contributes significantly to disease. Overall, the genes we highlight demonstrate strong conservation, refine pathogenic CNVs, define distinct functional pathways, and support the role of striatal networks in the pathogenicity of both ASD and ID/DD. Strikingly, the majority of the genes identified in this study present with DNMs in both ASD and ID/DD. While we expect a degree of diagnostic overlap^{21,22}, our results support a common genetic etiology among broad neurodevelopmental phenotypes. These genes are candidates for a genotype-first paradigm⁹⁸, where downstream follow-up of patients with the same *de novo* disrupted gene is likely to provide additional insight into unique phenotypic features associated with these different genetic subtypes⁹⁹ and additional support for their role in NDD.

METHODS

Data set:

We analyzed *de novo* single-nucleotide and indel variants from whole-exome sequencing (WES) data generated for 10,927 cases with neurodevelopmental diagnoses of ASD or ID/DD compiled in the denovo-db v.1.5 release²⁰ (Supplementary Table 1). The subset of denovo-db v.1.5 cohorts used was specifically chosen to avoid potential sample overlap as described in Geisheker et al.¹⁴ and in the release documentation for denovo-db v.1.5 (see

URLs). Briefly, we first assumed minimal overlap between studies based in Europe and America and studies with exclusion criteria, including participation in another study (e.g., SSC and the Autism Sequencing Consortium or ASC). This was supported by screening for individuals with shared mutational sites and second events¹⁴. We excluded studies from The Autism Simplex Collection or TASC due to known sample overlaps; additionally, we utilized only the more recent MSSNG data set³⁵ to avoid redundant annotations. All variants were annotated to RefSeq transcripts using SnpEff and collapsing to the most severe variant across isoforms. Variants were further binned into LGD (stop loss/gain, splice, and frameshift), missense, or synonymous categories for analysis. While these data are derived from a diverse set of WES platforms with differing sensitivities, our DNM-based analysis assumed samples to have perfect sensitivity. The combined set of 12,172 DNMs includes 2,357 LGD and 9,815 missense mutations, representing the largest such analysis to date. Each source study reports validated sites or validation rates ranging from 88.2% to 100% (with the exception of the DDD study, which opted for a high sensitivity approach) (Supplementary Table 1). Among these events, 1,106 LGD and 2,594 missense DNMs were validated/confirmed in the original studies while the remainder have unknown validation status (invalidated sites are not included in this analysis). CNV region data was obtained from a previous study of 29,085 children with developmental disorders and 19,584 population controls¹⁸ as well as a curated list of genomic disorders maintained by DECIPHER (v.9.18) (see URLs).

Statistics:

All standard statistical tests not reported by a described application (see relevant Methods) were performed using the R statistical language (v3.2.4), and non-parametric tests were used wherever possible. Wilcoxon rank-sum tests were used for distribution comparisons, with the exception of the Tukey Honest Significant Difference test for RVIS testing across all categories, and t-test for IQ comparisons. Fisher's exact test was used for all count comparisons. Likelihood ratio tests for goodness of fit were performed using one million multinomial sampling simulations. Multiple testing correction was applied where appropriate using either the Benjamini-Hochberg FDR or Bonferroni FWER as described in the relevant sections.

Recurrent variant analysis:

Enrichment of *de novo* LGD and missense variation per gene was calculated using two statistical models. The CH model as previously described¹¹ was run using the default setting and assuming a baseline rate of 1.8 *de novo* variants per individual (Supplementary Table 1). We note that ID/DD cohorts tend to have higher DNM rates than ASD cohorts, potentially relating to a combination of both technical (chosen sensitivity, platform differences) and biological biases, with the DDD cohort⁹ demonstrating the highest DNM rate among large cohorts²⁴. We anticipate that false positives would be randomly distributed and not enriched within specific genes. Observed coding DNM (LGD or missense) rates in the exome studies range from 0.87 to 1.36 among the large cohorts (Supplementary Table 1). While these variances in DNM rate likely influence our results, all rates are below the 1.8 DNM per individual rate used in the CH model; thus, overall our statistics will be conservative. In addition, we ran a recently published modified version⁴⁰ that separately tests for enrichment

of variants with CADD v.1.3 scores³⁹ of 30 and higher, which are predicted to be the most damaging of missense variation. Similarly, denovolyzeR¹² (R package version v0.2.0) was run using default settings. Each test (LGD, missense, MIS30) was individually adjusted to a q-value by the Benjamini-Hochberg procedure based on the number of genes in the model (exome wide) and genes with q-value < 0.05 and a DNM count of two or more were considered for the union set. Wherever necessary, gene symbols were adjusted to match those used in the individual models (CH model, denovolyzeR, CSEA). In cases where no model was generated for a gene of interest, “no model” is indicated in the significance column of Supplementary Table 2. Each analysis was corrected genome-wide for the number of genes present in the corresponding models (18,946 for CH model and 19,618 for denovolyzeR).

While the q-value threshold should control the FDR within a single list, the combination of two models has the potential to increase the upper bound of the FDR for both the union and intersection. Although we assume that the FDR should remain at 5% on average, the upper limits to the merged FDRs can be defined as follows:

$$FDR_{A \cup B} \leq \begin{cases} \frac{FDR_A \times |A| + FDR_B \times |B|}{|A \cup B|}, & \text{if } |B \setminus A| \geq FDR_B \times |B| \text{ AND } |A \setminus B| \geq FDR_A \times |A| \\ \frac{|B \setminus A| + FDR_A \times |A|}{|A \cup B|}, & \text{if } |B \setminus A| < FDR_B \times |B| \text{ AND } (|A \setminus B| \geq FDR_A \times |A| \text{ OR } |B \setminus A| < |A \setminus B|) \\ \frac{|A \setminus B| + FDR_B \times |B|}{|A \cup B|}, & \text{if } |A \setminus B| < FDR_A \times |A| \text{ AND } (|B \setminus A| \geq FDR_B \times |B| \text{ OR } |A \setminus B| \leq |B \setminus A|) \end{cases}$$

$$FDR_{A \cap B} \leq \begin{cases} \frac{FDR_A * |A|}{|A \cap B|}, & \text{if } |A| \leq |B| \text{ AND } |A \cap B| \geq FDR_A * |A| \\ \frac{FDR_B * |B|}{|A \cap B|}, & \text{if } |B| \leq |A| \text{ AND } |A \cap B| \geq FDR_B * |B| \end{cases}$$

Application of these upper bounds estimates the maximal error rates in the unions as LGD FDR < 8.59%; Missense FDR < 7.56%. As MIS30 is only examined by one model, its estimated FDR remains at 5%. Similarly, we estimate the maximal error rates in the intersections as LGD FDR < 5.7%; Missense FDR < 6.75%. We wish to stress that we anticipate these to be upper bounds. In addition to the described treatment, to increase the stringency of our union set, we excluded any gene with a single DNM from further consideration. As a result, we discarded q-values for 1,183 LGD, 4,246 missense, and 1,083 MIS30 genes of which 113 reach corrected significance but are primarily small genes. This represents elimination of ~5-15% of the genes further reducing the overall FDR. Despite their likely enrichment for false positives, 11 of 113 single-hit genes have been previously implicated in an NDD (Supplementary Table 2) and are thus potentially of interest for future studies with additional samples.

Identification of novel genes:

To address novelty, we considered statistically significant genes as defined by five recent publications involving large-scale exome, whole-genome, or targeted sequencing (DeRubeis et al.²⁶, Sanders et al.¹⁹, an in-press revised version of Stessman et al.¹⁰, Yuen et al.³⁵, DDD 2017²⁴) and three well-curated databases (OMIM, SFARI Gene, and ID Gene Database

Project, see URLs; all database queries made on 02/19/2018). We undertook the following approach to ‘novelty’ when comparing these data sets to our list of 253 significant genes. Any gene listed as significant (regardless of thresholds or alternative methods of significance (CNV integration, private variation, inherited variation)) in any of these data sets was not considered ‘novel’ in our data set. Additionally, we considered SFARI genes of any score category as known. For the 80/253 genes not “known” by this initial screen, we followed up with literature searches for evidence of any link to case reports or human studies of ID, autism, or mental retardation, or DD. For 49/80 genes, no evidence was found through the PubMed search; this represents our most conservative set of ‘novel’ genes (Supplementary Table 3). While this pool is the most likely to contain false positive findings, 10 of these 49 genes were also significant under an FWER correction (*SMARCD1*, *SNX5*, *TNPO2*, *ADAP1*, *CAPN15*, *CHD3*, *TMEM178A*, *AGO4*, *SNAPC5*, and *ANP32A*). Clinical evidence, even single case reports, adds credence to our gene list as high-confidence candidates for NDD pathology.

Network analysis:

Identification of clustered gene modules was performed using the MAGI (merging affected genes into integrated networks)⁴³ enrichment tool with default settings, followed by visualization incorporating co-expression and physical interaction data from geneMANIA¹⁰⁰. Significance for MAGI modules was performed by permuting DNM across genes according to their mutation rates in the CH model 100 times and enumerating the number of random modules with scores greater than or equal to the module of interest.

Expression analysis in mouse:

Functional enrichment was examined using the CSEA and TSEA tools⁴⁸. CSEA⁴⁸ was additionally applied to candidate genes using single-cell transcriptomic profiling data from mouse cortex and hippocampus¹⁰¹ using custom R scripts. Raw mRNA count data was downloaded from (see URLs, and only genes with at least 25 total molecules and at least 1 molecule in 100 cells were retained. Molecule counts were then incremented by a pseudo-count of 0.125 and RPKM-normalized. RPKMs were averaged over each of the 47 cell subclasses identified by the authors using the BackSPIN clustering algorithm. Significantly enriched transcripts in each subclass were identified using the pSI package⁴⁷ with a minimum expression value of 3 RPKM and default settings otherwise.

Expression analysis in humans:

15,928 single nuclei were isolated from the middle temporal gyrus of adult post-mortem brains of three human donors and profiled with RNA-sequencing. Raw read (fastq) files were aligned to the GRCh38 human genome sequence (Genome Reference Consortium, 2011) with the RefSeq transcriptome version GRCh38.p2 (current as of 4/13/2015). For alignment, Illumina sequencing adapters were clipped from the reads using the fastqMCF program (ea-utils, see URLs). After clipping, the paired-end reads were mapped using Spliced Transcripts Alignment to a Reference (STAR)¹⁰² with default settings. Unsupervised clustering identified 71 distinct transcriptomic clusters, including 41 GABAergic (inhibitory) neuronal, 24 glutamatergic (excitatory) neuronal, and 6 non-neuronal cell types (unpublished). For each gene, the expression pattern was characterized as the number of cell

types with appreciable expression (median counts per million [CPM] > 1) in three broad classes: inhibitory and excitatory neurons and glia. Heatmaps were constructed of log-normalized expression ($\log_2\text{CPM} + 1$) of NDD risk genes and control genes across cell types. The number of inhibitory and excitatory neuronal and glial types that expressed NDD risk genes and control genes were quantified and visualized as empirical cumulative distributions. Distributions were compared with two-sided Wilcoxon rank-sum tests for each broad class of cell types, and p-values were Bonferroni corrected for multiple testing. A cell type specificity or marker score (beta) was defined for all genes to measure how binary expression was among clusters, independent of the number of clusters labeled. First, the proportion (x) of samples in each cluster that expressed a gene above background level (CPM > 1) was calculated. Then, scores were defined as the squared differences in proportions between all pairs (i,j) of n clusters normalized by the sum of absolute differences plus a small constant (ϵ) to avoid division by zero. Scores ranged from 0 to 1, and a perfectly binary marker had a score equal to 1.

$$\beta = \frac{\sum_{i=1}^n \sum_{j=1}^n (x_i - x_j)^2}{\sum_{i=1}^n \sum_{j=1}^n |x_i - x_j| + \epsilon}$$

Shapiro-Wilk tests rejected ($p < 0.05$) the null hypothesis that distributions were normally distributed of cell type counts for each broad class, maximum average expression, and marker scores. Therefore, distributions were compared with two-sided Wilcoxon rank-sum tests, and p-values were Bonferroni corrected for multiple testing.

Projected rates of gene discovery:

Prediction of future LGD and missense variation discovery rates was determined by sampling (with replacement) populations of 100 to 10,900 cases 10,000 times each and calculating DNM statistics using the CH model. The number of genes with two or more mutations and a q-value below 0.05 were then enumerated for each simulation and linear as well as logistic growth models were fit to each curve with the best model being chosen by BIC. Model fits and confidence bounds were performed using the base stats and propagate (see URLs) packages in the R statistical language.

Figure 1: *de novo* enriched genes and their characteristics.

Shown are the results of applying both the chimpanzee-human (CH) divergence model and denovolyzeR to *de novo* variation in $n = 10,927$ independent individuals with ASD/ID/DD. The two models show considerable gene overlap (**A,B**) with correlated significance values (LGD Pearson $r^2 = 0.94$, missense $r^2 = 0.74$) (**C,D**). CH model LGD outliers include *NONO*, *MEIS2*, *LEO1*, *WDR26*, and *CAPRIN1*, and denovolyzeR LGD outliers include *ZBTB18* and *FAM200B* (**C**). CH model missense (MIS) outliers include *CAPN15*, *SNAPC5*, *DLX3*, *TMEM178A*, *ADAPI1*, *SNX5*, *SMARCD1*, *WDR26*, and *AGO4*, and denovolyzeR missense outliers include *ITPR1*, *RAC1*, *SETD1B*, *WDFY4*, and *UNC80* (**D**). Recurrent mutated LGD genes (TRUE, $n = 145$ with pLI scores) are highly enriched for genes intolerant to mutation as defined by ExAC pLI score (two-tailed Wilcoxon rank-sum test) (**E**). Genes significantly enriched for missense DNMs ($n = 118$ with missense Z scores) are outliers by the ExAC missense depletion Z scores (two-tailed Wilcoxon rank-sum test) (**F**). Similarly, all subcategories of significant genes (n below each category name) are intolerant to mutation (RVIS percentile) when compared to non-significant genes (Tukey HSD test, p-values are corrected for all possible group comparisons) (**G**). Boxplots represent Quartiles 1 to 3 with the median indicated. Whiskers span from $Q1 - 1.5 \text{ IQR}$ to $Q3 + 1.5 \text{ IQR}$.

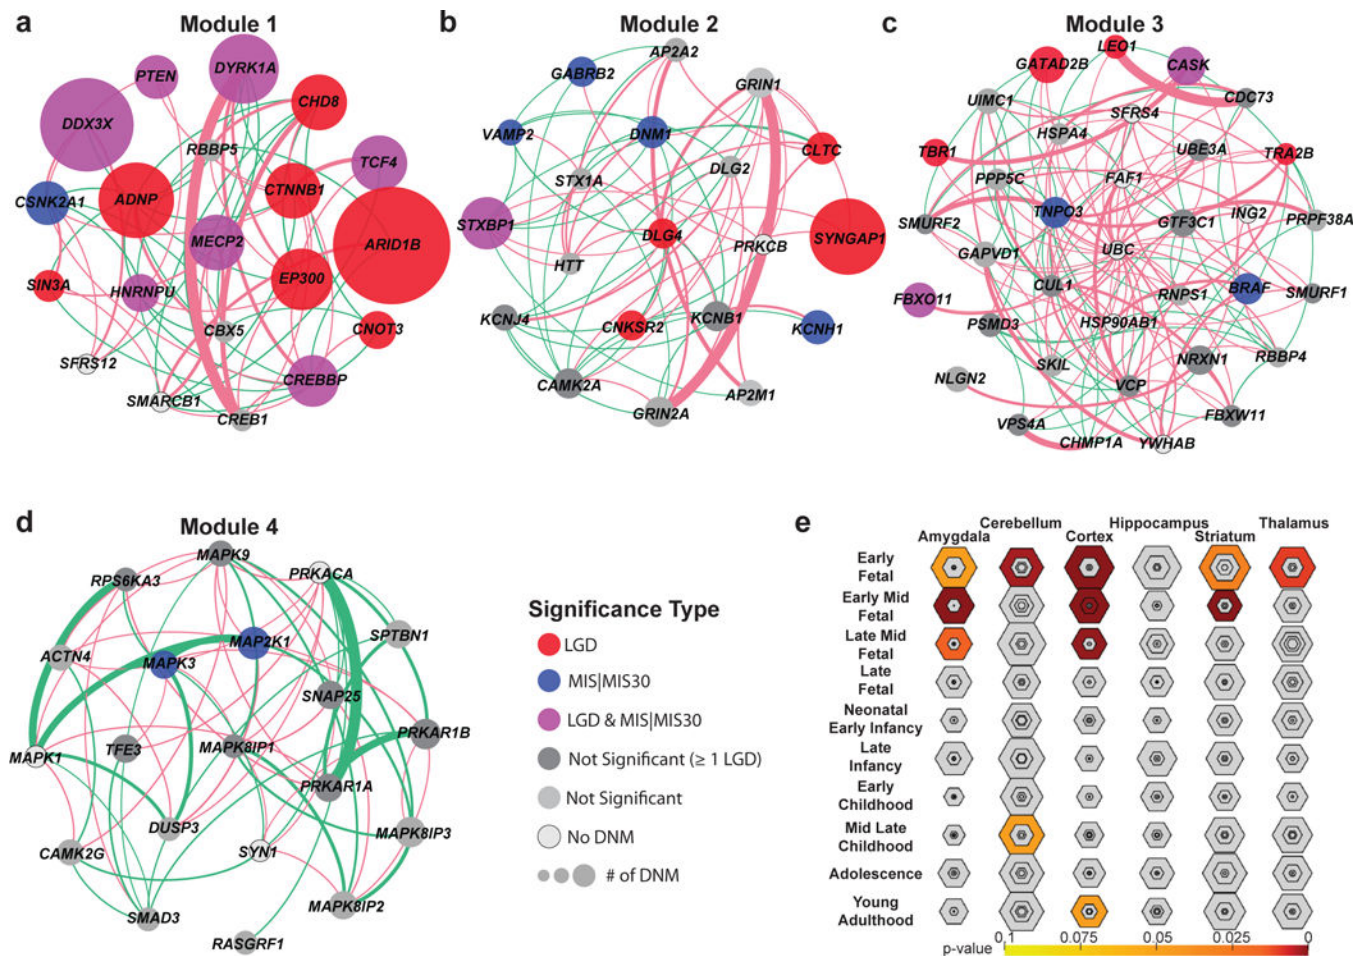

Figure 2: Gene expression and protein-interaction networks. (A-D) MAGI⁴³ analysis of the union set ($n = 253$ independent genes) highlights the top four modules of co-expression and protein-protein interaction (PPI), including genes significant for DNM enrichment by denovolyzeR (FDR-adjusted Poisson test) or the CH model (FDR-adjusted binomial test) (colored circles) and new candidate genes with DNM that do not yet reach significance (dark gray). The size of the circle represents the relative number of patients with DNMs within this cohort. Edges depict PPIs (pink arcs) and co-expression (green arcs) scaled by their scores from geneMANIA¹⁰⁰. (E) Tissue-specific enrichment analyses (TSEA) of the union set ($n = 253$ independent genes) highlight a strong bias to various developing parts of the brain with the strongest signal early to mid-fetal development (color corresponds to FDR-adjusted one-tailed Fisher’s exact test p-values, shaded regions closer to the center of each hexagon indicate increasing tissue specificity).

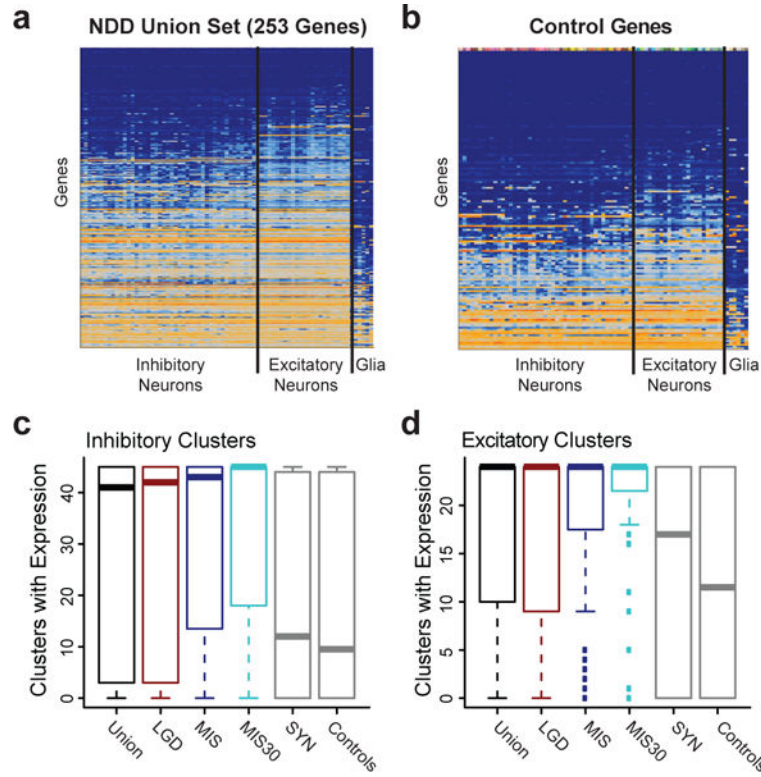

Figure 3: Expression in human cortical neurons.

(A-B) Heatmaps demonstrating a broad pattern of inhibitory and excitatory neuronal expression (median log₂(CPM+1)) in the union gene set (n = 253 independent genes) compared to control genes (n = 156 independent genes). Expression level is indicated by a color gradient from low expression (dark blue) to high (orange). Rows represent individual genes and are ordered by the number of clusters (transcriptomic defined cell types) with expression (median CPM > 1), and columns represent 41 inhibitory neuronal, 24 excitatory neuronal, and 6 glial transcriptional clusters, each representing a distinct cell type. (C-D) The number of inhibitory and excitatory clusters with expression in NDD genes (Union n = 253, LGD n = 145, MIS n = 123, MIS30 n = 59) compared to controls (synonymous (SYN) n = 101, Control n = 156 independent genes). The signal is strongest for NDD genes with the most severe missense mutations (MIS30). Boxplots represent Quartiles 1 to 3 with the median indicated. Whiskers span from Q1 - 1.5 IQR to Q3 + 1.5 IQR.

Figure 4: Estimation of gene discovery rates in future cohorts.

We estimate the number of genes reaching significance under the CH model at varying population sizes subsampled from the total cohort of 10,927 individuals. Both the number of significant genes with recurrent LGD and MIS30 DNMs appear to be saturating with limited new gene discovery as sample sizes grow. *De novo* missense variants (including MIS30), however, as a more general class demonstrate a more complex growth pattern with no best-fit line and, thus, likely represent the most important reservoir for new gene discovery as sequence data are generated from additional ASD and DD cohorts.

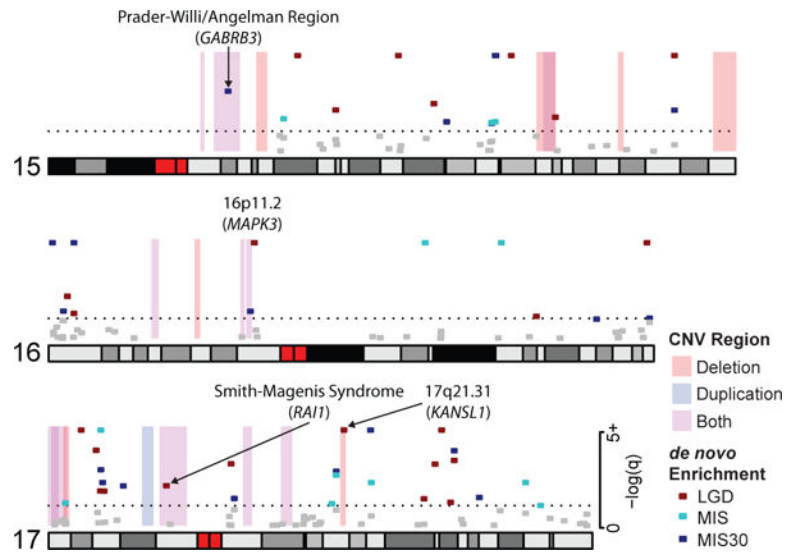

Figure 5: Integration of *de novo* SNVs and CNV morbidity map.

Shown are examples of pathogenic CNVs (blue, red and purple shading) associated with genomic disorders from chromosomes 15, 16, and 17, which intersect with genes that show a significant excess of DNM in $n = 10,927$ independent patients (red, turquoise and blue points representing the minimum q-value from either denovolyzeR or CH model, the dashed line represents a q-value of 0.05). The analysis confirms known associations, such as *RAI1*, and *KANSL1* and candidate association for *MAPK3*. Recurrent severe missense mutations of *GABRB3* have been associated with autism and may be relevant to the recurrent 15q11 duplication. We note that mutations and deletions of the imprinted genes *SNRPN* (no DNM in our data set) and *UBE3A* (1 LGD and 1 missense DNM in our data set) are known to cause the core phenotype of Prader-Willi and Angelman syndromes, respectively, but do not reach significance in this analysis.

Table 1:

Recurrent DNM gene summary and model comparison.

Variant Category	CH Model Count	denovolyzeR Count	Union Count (FDR (FWER))	Intersection Count (FDR (FWER))	ID/DD Only Union Count (FDR (FWER))	ASD Only Union Count (FDR (FWER))
LGD & MIS30 & Missense	14	NA	14 (5)	NA	4 (1)	0 (0)
LGD & MIS30	1	NA	1 (3)	NA	0 (0)	0 (0)
LGD & Missense	13	22	15 (6)	21 (8)	19 (10)	3 (1)
LGD	92	108	115 (62)	85 (49)	95 (55)	31 (14)
MIS30 & Missense	28	NA	31 (18)	NA	9 (7)	0 (0)
MIS30	16	NA	14 (10)	NA	0 (0)	0 (0)
Missense	46	63	63 (20)	42 (22)	56 (25)	7 (3)
<i>total</i>	210	193	253 (124)	148 (79)	183 (98)	41 (18)

The number of genes reaching statistical significance for DNM enrichment in $n = 10,927$ independent samples by the CH model and denovolyzeR as well as the unions and intersections of these gene sets are shown for each mutation category (LGD, Missense, MIS30). Also shown are the union counts for the ASD ($n = 5,624$ independent samples) and ID/DD ($n = 5,303$) only analyses. Counts represent genes passing an FDR q-value threshold of 0.05. Bracketed numbers represent genes passing a Bonferroni FWER correction ($p < 5e-7$).

Genes enriched for *de novo* variation in 10,927 ASD/ID/DD patients in denovo-db v.1.5.

DNM counts and significance categories from n = 10,927 independent samples are shown for genes from the union significance set (n = 253 genes denovozyeR or CH model FDR < 5%) that intersect a previously established genomic disorder region. Gene symbols with underlines represent confirmation of known CNV associations. SD: segmental duplication

⁷DECIPHER syndrome classification system; see URLs.

¹⁸.SATB2 is significant both by focal deletions and as part of the 2q33.1 region.
