NeuroCure Clinical Research Center and Clinical and Experimental Research Center for Multiple Sclerosis, Charité – Universitätsmedizin Berlin, Berlin, Germany

Abstract: Multiple sclerosis (MS) is a common inflammatory demyelinating disorder of the central nervous system. It frequently affects females in their reproductive phase of life. Therefore, family planning, pregnancy, and breastfeeding are important issues in the management of MS, particularly with respect to counseling and drug treatment. This paper reviews currently available data on the outcome of pregnancies in MS patients and the influence of pregnancy on the course of the disease. We give an update on the use of various disease-modifying MS drugs during pregnancy and breastfeeding. In addition to established therapies such as interferon- β , glatiramer acetate, natalizumab, and fingolimod, we also discuss the state of knowledge about new agents such as dimethyl fumarate, teriflunomide, and alemtuzumab in the context of pregnancy and breastfeeding.

Keywords: multiple sclerosis, pregnancy, lactation, disease-modifying therapy

Introduction

Multiple sclerosis (MS) is the most common chronic inflammatory disorder of the central nervous system during young adulthood.¹ Simplified infiltration of autoreactive lymphocytes leads to the formation of inflammatory plaques in the brain and spinal cord characterized by demyelination and neurodegeneration, which result in transient neurologic dysfunction. Thereafter, diffuse axonal and neuroaxonal degeneration leads to an ongoing accumulation of neurologic deficits. Both genetic and environmental factors are considered to be involved in the pathogenesis of MS.¹ Women are more frequently affected than men. In some regions, especially in countries of northern latitude, the male to female ratio is as high as 1:4.5.²⁻⁴ Because many MS patients are of fertile age, family planning and pregnancy can become relevant issues during the disease course.

Reasonably, many women with MS who plan to conceive or are already pregnant consult their obstetrician for advice. Unfortunately, obstetricians are not usually experienced in MS. Conversely, many neurologists have only limited knowledge of obstetrics and pregnancy in MS.⁵ For this reason, it may be difficult for MS patients to get competent advice on the influence of MS on pregnancy, birth, and lactation, or on the effect of pregnancy on the MS disease course.

This paper summarizes current knowledge on the influence of pregnancy and lactation on MS and addresses the question of whether having MS influences the course and outcome of pregnancy. In particular, we give an overview of current recommendations on the use of disease-modifying drugs (DMDs) during pregnancy and lactation.

Further pregnancy-related issues, such as inheritance risk, fertility, and reproduction techniques, are beyond the scope of this paper and are addressed elsewhere.^{6,7}

Influence of pregnancy on MS

Numerous studies have investigated the influence of pregnancy on the MS disease course. In 1998, the PRIMs (Pregnancy in Multiple Sclerosis) study examined the course of 269 pregnancies in 254 MS patients in a prospective manner.⁸ The authors showed that the relapse rate decreases during pregnancy and reaches a nadir in the third trimester. However, in the first months after delivery, the relapse rate increased to a higher level than before pregnancy. Six to 9 months after delivery, the relapse rate decreased to prepregnancy rates. Further studies subsequently confirmed these results.^{9,10} Whether relapses in the year before and during pregnancy represent a risk factor for postpartum relapse is not yet conclusive.^{11,12}

The immunologic mechanisms responsible for the decrease in disease activity during pregnancy are still poorly understood. It is supposed that immunologic changes aimed at protecting the fetus from maternal immune defense contribute to the observed reduction in disease activity. A T-helper 1 to T-helper 2 cell shift is often discussed in the literature,^{13,14} although current data suggest that the mechanisms are more complex. Changes in CD56^{bright} natural killer cells,¹⁴ interferon gamma (IFN- γ)-producing CD4+ T-cells,¹⁵ in the CD4+/CD8+-ratio,¹⁶ and in interleukin-8 serum levels¹⁷ have been described during pregnancy. Moreover, regulatory T-cells seem to play an important role in modulating disease activity during pregnancy in MS.¹⁸⁻²¹ Further studies are necessary to investigate the underlying cellular and molecular mechanisms.

Influence of MS on pregnancy and childbirth

Many female MS patients are concerned that the disease may have a negative impact on pregnancy or childbirth. In 2011, a meta-analysis evaluated the results of 22 studies between 1983 and 2009, and included a total of more than 13,000 pregnancies in mothers with MS.²² The rates of abortion, prematurity, malformation, and neonatal death in MS patients were comparable with those in healthy mothers. Although some surveys revealed a slight reduction in birth weight of between 108 g and 123 g,^{23,24} an elevated risk of low birth weight (<2,500 g) in newborns of MS mothers was not detected in the meta-analysis.²² Another survey studying 432 births in 321 MS patients showed no differences in birth weight, mean gestational age, labor duration, or 5-minute

Apgar score.²⁵ Except for a higher rate of maternal anemia, no other pregnancy-related complications, including gestational diabetes mellitus or preeclampsia, were recorded.²⁶

In healthy women, rates of primary cesarean section in various countries show great variability and are influenced by religious, social, and cultural values. It is therefore not surprising that cesarean delivery in MS mothers shows wide regional differences, ranging from 10% to 40%.²² Some studies found no elevated rates of cesarean section in MS,^{25,26} whereas others revealed a higher rate of cesarean delivery when compared with the general population.^{23,27} Importantly, the higher rate of cesarean section in MS was due to an increase in planned and not emergency deliveries.²³

On the one hand, a cesarean section may in fact be beneficial because it can be performed electively; there is no pain during childbirth, and the risks of retained placenta and urinary incontinence are lower. On the other hand, a cesarean delivery carries a greater risk of injury to the uterus, bladder, or ureter, and longer hospitalization. Many MS patients and physicians may favor a cesarean section as they are concerned that spasticity, neuromuscular perineal weakness, or exhaustion in the context of MS could complicate a natural delivery. In rare cases, these may actually be reasons for planning an elective cesarean section. However, given that the number of emergency cesarean sections in MS does not exceed that in healthy women, the fact alone of suffering from MS should not, in our opinion, be a reason to choose cesarean section over vaginal delivery if no other obstetric reasons exist.

Some surveys have revealed higher rates of operative delivery with the use of forceps or vacuum extraction in MS patients^{23,26,28} due to exhaustion and slow progression of delivery. MS patients should therefore be informed about these issues. In 1998, Confavreux et al found no impact of epidural analgesia on the postpartum relapse rate in MS.⁸ Another study in 2012 confirmed these results.²⁹ MS patients should therefore be advised that MS per se is no reason to abstain from epidural analgesia.

Disease-modifying drugs during pregnancy

Over approximately 25 years, an increasing number of drugs have been made available for immunomodulatory therapy in MS. The most experience is with interferon beta (IFN- β) and glatiramer acetate (GA), which are administered subcutaneously. In patients with adverse effects or high disease activity, escalation with intravenous natalizumab once a month or orally administered fingolimod, a sphingosine receptor modulator, is feasible. For patients with secondary

progressive MS, mitoxantrone is a possible treatment option. Recently, teriflunomide, dimethyl fumarate (DMF), and alemtuzumab have been made available as further therapy options in relapsing–remitting MS.

Managing DMDs in the context of conception and pregnancy poses a challenge for both MS patients and attending physicians. On the one hand, unnecessary risks to the child should be avoided; on the other, patients left without medication are subject to a higher risk of MS relapse. To date, none of the DMDs available for MS has been approved for use during pregnancy. The current data are primarily derived from MS pregnancy registries and are often collected retrospectively. Therefore, it is difficult to give evidence-based recommendations for MS treatment during pregnancy. The United States Food and Drug Administration (FDA) pregnancy categories can be used as a reference for decision-making (Table 1). According to that classification, GA is considered to be the safest of the currently available MS drugs. It is assigned to category B, whereas IFN- β , natalizumab, and fingolimod are classified one category lower. We describe in detail below the data currently available for the different drugs and their use during pregnancy.

Intravenous methylprednisolone

Relapses in MS are commonly treated with high-dose methylprednisolone given intravenously on 3–5 consecutive days. Glucocorticoid therapy accelerates recovery, but does not

seem to have an impact on the level of remission finally achieved.³⁰

Methylprednisolone is classified within category C by the FDA (Table 1). The manufacturers indicate that during pregnancy, especially in the first trimester, methylprednisolone should be used only after a thorough risk–benefit analysis. Animal studies showed higher risks of cleft palates and intrauterine growth disturbances. Adequate studies in human pregnancy are lacking.

An elevated risk of oral clefts has been described in pregnant women suffering from inflammatory bowel disease, bronchial asthma, or lupus erythematosus who were given glucocorticoids during the first trimester.³¹ Another study showed lower gestational age, decreased birth weight, and higher rates of miscarriage after exposure to glucocorticoids in the first trimester.³² In light of these findings, we recommend discussing the use of glucocorticoids during the first 3 months of pregnancy very critically. Use of such medication during this period should be reserved for severe MS relapses. Treatment with glucocorticoids during the second and third trimesters does not seem to be harmful to the fetus.³³

Interferon beta

Since the mid-1990s, IFN- β has been approved for subcutaneous or intramuscular immunomodulatory therapy of MS. IFN- β leads to a reduction in relapse rate of approximately

Table 1 US Food and Drug Administration pregnancy categories

FDA pregnancy category	Description	Drug
B	Animal studies have revealed no evidence of harm to the fetus; however, there are no adequate and well controlled studies in pregnant women. OR Animal studies have shown an adverse effect, but adequate and well controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.	Glatiramer acetate
C	Animal studies have shown an adverse effect and there are no adequate and well controlled studies in pregnant women. OR No animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.	IFN- β Natalizumab Fingolimod Dexamethasone Prednisolone IVIG Dimethyl fumarate Cyclosporin A
D	Adequate well controlled or observational studies in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.	Cyclophosphamide Azathioprine Mitoxantrone
X	Adequate well controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks. The use of the product is contraindicated in women who are or may become pregnant.	Methotrexate Teriflunomide

Abbreviations: IVIG, intravenous immunoglobulin G; FDA, US Food and Drug Administration; IFN- β , interferon beta.

30%³⁴ and decreases the progression of disability in long-term follow-up.³⁵

The FDA classifies IFN- β within category C because animal studies have shown adverse effects on the fetus, and no adequate studies in pregnant women exist (Table 1). According to the German manufacturing information, it is explicitly contraindicated to start IFN- β therapy during pregnancy due to a potentially elevated risk of spontaneous abortion. Patients with a high relapse rate who are already undergoing treatment with IFN- β are advised to weigh the risk of severe relapse after discontinuation of IFN- β against the risk of spontaneous abortion.

Currently, IFN- β can be considered the DMD with the largest experience of use in pregnant women with MS. In the literature, data from approximately 1,000 pregnancies with IFN- β exposure at the time of conception and at least the first weeks of pregnancy are currently available. Table 2 provides an overview of a number of studies on birth outcome after exposure to IFN- β . In 2012, a systematic review by Lu et al summarized the results of several studies on the safety of DMDs during pregnancy.³⁶ A total of 761 pregnancies with

IFN- β exposure were included. The authors associated IFN- β exposure with preterm birth as well as lower birth weight and length. However, no elevated risks of spontaneous abortion, birth weight under 2,500 g, cesarean section, or congenital abnormalities were described.

Some authors, including Lu et al,^{35,36} advise women to discontinue DMD when they plan to conceive. In contrast, Schröder and Schilli point out that since June 2006 an IFN- β treatment-free interval before a planned pregnancy is no longer recommended by the European Medicines Agency.³⁷ Based on the data currently available, intake of IFN- β during the conception period and the first weeks of pregnancy seems to be relatively safe. It has become increasingly common to continue IFN- β until pregnancy has been confirmed. Given that it is not known when gestation will start, this approach seems to be justified, particularly in patients with high disease activity. However, continuation of IFN- β treatment throughout pregnancy should be considered very carefully. Only a small number of cases involving IFN- β therapy over the course of the entire pregnancy is available in the current literature.^{38,39} In these studies, all

Table 2 Studies on birth outcome after exposure to interferon beta

Year	Authors	Pregnancies (n)	Results
2005	Boskovic et al ⁸⁴	23	Increased rate of spontaneous abortion (39%); decreased birth weight (~-3,190 g); two major birth defects (Down syndrome, X chromosome abnormality)
2005	Sandberg-Wollheim et al ⁸⁵	41	Normal spontaneous abortion rate, one birth defect (hydrocephalus)
2008	Patti et al ⁸⁶	14	Normal spontaneous abortion rate; normal birth weight; shorter gestational period (37.8 weeks), no malformations
2009	Hellwig et al ⁸⁷	17	Normal miscarriage rate (12%), normal birth weight
2009	Weber-Schoendorfer and Schaefer ⁴⁴	69	Higher rate of spontaneous abortion for IFN- β 1b (28%) compared with IFN- β 1a (5%) but normal spontaneous abortion rate in combined IFN- β cohort; lower birth weight (~-2,330 g)
2010	Amato et al ⁸⁸	88	Lower birth weight (~-3,000 g); decreased birth length (~-49 cm); higher rate of preterm delivery (33% versus 20%); normal rate of spontaneous abortion; no major birth defects
2010	Coyle et al ⁸⁹	69	Normal spontaneous abortion rate; three birth defects (trisomy 21, multiple hemangiomas, cardiovascular defect, and hip dysplasia)
2011	Sandberg-Wollheim et al ⁹⁰	425	Normal spontaneous abortion rate; three major birth defects (VACTERL syndrome, Tetralogy of Fallot, solitary kidney)
2011	Finkelsztejn et al ¹⁰	69	One case of delayed intrauterine growth; two malformations (Dandy-Walker-syndrome, ventriculomegaly); two cases of neonatal jaundice
2011	Hellwig and Gold ³⁸	7	Exposure throughout pregnancy; normal birth weight; no preterm delivery; one malformation (valvular stenosis of pulmonary artery)
2012	Lu et al ⁴⁸	15	Trend to higher risk for assisted vaginal delivery; normal rate of cesarean section; normal birth weight gestational age and Apgar score; no congenital abnormalities
2012	Richman et al ⁹¹	298	30 spontaneous abortions; 27 birth defects (no details given)
2012	Hellwig et al ⁵⁰	78	Normal birth weight and length; three birth defects (ventricular septal defect, valvular stenosis of the pulmonary artery, hip dysplasia)
2013	Fragoso et al ⁴⁹	17	Normal rate of obstetric complications; lower birth weight (~-2,760 g) and length (~-47 cm); lower postpartum relapse rate and EDSS progression in women with >8 weeks of exposure during pregnancy
2014	Dung and Panda ³⁹	1	Exposure throughout pregnancy; normal birth weight; no congenital anomaly

Abbreviations: EDSS, Expanded Disability Status Scale; IFN, interferon; VACTERL, Vertebral anomalies, Anal atresia, Cardiac defects, Tracheoesophageal fistula and/or Esophageal atresia, Renal & Radial anomalies and Limb defects.

patients delivered newborns of normal birth weight and gestational age. However, one baby had valvular stenosis of the pulmonary artery. The causal relationship between this malformation and intrauterine IFN- β exposure is not clear. Obviously, these data are not sufficient to make any therapy recommendations.

Glatiramer acetate

GA was approved in 1996 as a DMD for relapsing-remitting MS in the USA, and European Union approval was granted 5 years later. GA reduces the MS relapse rate by approximately 30%⁴⁰ and the number of enhancing magnetic resonance imaging (MRI) lesions to the same extent.⁴¹ Moreover, a 45% risk reduction in conversion from clinically isolated syndrome to clinically definite MS was reported in the Pre-CISE study (ClinicalTrials.gov identifier NCT00666224).⁴²

According to the FDA classification (Table 1), GA is considered the safest DMD during pregnancy in MS. This classification is based on there being no evidence of fetal harm in animal studies, although adequate and well controlled studies in pregnant women are lacking. Compared with IFN- β , considerably fewer studies exist with respect to safety during pregnancy. In the pivotal clinical trials and post-marketing period until 2003, 250 pregnancies were recorded. The rates of spontaneous abortions and major congenital anomalies were described to be in the range of the general population.⁴³ In addition, approximately 200 pregnancies under treatment with GA are described in the literature. These studies revealed a normal spontaneous abortion rate,^{44–47} mean birth weight,^{10,44–50} and gestational age.^{10,44,47,48,50} Some studies, however, described preterm delivery,³⁸ one case of neonatal death,⁴⁹ and a reduction in birth weight³⁸ and length.⁴⁹ Reported congenital anomalies were, for example, penile hypospadias,³⁸ clubfoot,⁴⁴ atrioventricular canal defects,⁴⁴ bone malformations,⁴⁹ abnormality of urinary bladder valves,⁵⁰ and hip dysplasia.⁵⁰ However, the number, severity, and nature of congenital malformations did not exceed the range expected in the general population.

Whether GA should be discontinued before a planned conception is controversial in the literature. In light of the limited data, some authors recommend discontinuation as soon as conception is planned,³⁶ whereas others caution against leaving patients untreated while waiting for conception.⁵¹

In line with most expert opinion and guidelines, and similar to the approach with IFN- β , we recommend patients continue treatment with GA until pregnancy has been confirmed, particularly in patients with a high relapse rate before pregnancy.

In any case, the possible risks and benefits have to be weighed individually, taking into account the viewpoint of the patient and lack of available data at present.

Natalizumab

Natalizumab is a monoclonal antibody used in the treatment of MS patients with high disease activity and those in whom IFN- β or GA has had an insufficient effect. Studies have shown a reduction in the annualized relapse rate of up to two thirds^{52,53} and a significant reduction in gadolinium-enhancing lesions.^{53,54}

The largest data collection on pregnancy outcome after exposure to natalizumab comes from the Tysabri® (natalizumab) Pregnancy Exposure Registry.⁵⁵ More than 350 pregnancies with exposure to natalizumab within 90 days prior to the last menstrual period were followed. In 28 of these pregnancies, major and/or minor birth defects were observed, which is comparable with the rate detected by active birth registries in the general population.⁵⁶ The rate of spontaneous abortion corresponded to the frequency in the general population.

Apart from this registry, approximately 40 patients receiving treatment with natalizumab during pregnancy are described in the literature.^{57–60} In two of the studies, natalizumab was continued until the third trimester or even throughout the pregnancy.^{59,60} These studies reported normal rates of spontaneous abortion and congenital malformation, and normal birth weight and length. Another case report described normal Apgar score, birth weight and length, and head circumference in two newborns with mothers who took natalizumab until week 34 of pregnancy.⁶¹ However, a reduction in CXCL12-induced T-cell chemotaxis was found in both of these children, which might compromise the neonatal immune system and be associated with an increased risk of infection.

Compared with IFN- β and GA, it is even more difficult to give advice about treatment with natalizumab in the context of a planned pregnancy. On the one hand, until now, there has been no conclusive evidence for an increased risk of adverse pregnancy outcomes. Moreover, discontinuation of natalizumab in the context of a planned pregnancy carries the risk of a rebound of disease activity.⁶² On the other hand, the data currently available are insufficient to rule out rare complications. Therefore, treatment with natalizumab should be stopped at the latest when pregnancy has been detected. After carefully assessing the potential risks and benefits, continuing treatment around the time of conception or even pregnancy can be taken into consideration. In contrast with

IFN- β , the manufacturer of natalizumab does not rule out use of the drug during pregnancy when necessary due to the clinical condition of the patient.

Fingolimod

Fingolimod acts as a sphingosine receptor modulator and has been approved for highly active relapsing-remitting MS in Europe since March 2011. Compared with placebo, it leads to a decrease in the annualized relapse rate of more than 50% and significantly reduces the number of gadolinium-enhancing lesions seen on MRI.⁶³ In animal studies, fingolimod showed teratogenic effects, with increased rates of visceral malformation, eg, persisting truncus arteriosus or ventricular septal defect. Further, fetal growth retardation and an increase in embryofetal mortality were observed. For this reason, the manufacturer's information advises against becoming pregnant during and for up to 2 months following treatment with fingolimod, and to stop fingolimod therapy immediately when an unplanned pregnancy is detected.

The outcomes of 127 pregnancies from the clinical trials and post-marketing experience of fingolimod were presented at the European Committee for Treatment and Research in Multiple Sclerosis meeting in October 2012.⁶⁴ In these pregnancies, 21 spontaneous and 40 induced abortions were reported. Five congenital anomalies and three other pregnancy abnormalities occurred. This corresponds to the expected frequency in the general population. Out of this cohort, 66 pregnancies with in utero exposure to fingolimod are currently published.⁶⁵ To collect further data, a multinational fingolimod pregnancy registry has been established.

Mitoxantrone

Mitoxantrone is an intercalating agent that leads to disturbances in DNA synthesis and repair mechanisms. It is approved in Europe for progressive relapsing and secondary progressive MS. Mitoxantrone therapy may result in improvements of disability, changes in the ambulation index, and a reduction in the number of treated relapses.⁶⁶

Mitoxantrone is known to be mutagenic. The FDA classifies mitoxantrone within category D because of the known risks to the fetus, but in individual cases the potential benefit may outweigh the risk. The manufacturer's information indicates that in the event of an unplanned pregnancy during treatment with mitoxantrone, genetic counseling should be provided. In the literature, two case reports describe the pregnancy outcome after in utero exposure to mitoxantrone in MS patients.^{67,68} In one case, restricted growth without evidence of congenital malformation was

reported.⁶⁷ The other study described a newborn with Pierre Robin sequence, a congenital malformation with cleft palate, micrognathia, and glossoptosis attributable to mitoxantrone exposure.⁶⁸ Both males and females are advised to wait at least 6 months after discontinuing mitoxantrone therapy before starting unprotected sexual intercourse. Moreover, before beginning treatment, male MS patients should be informed about the possibility of cryopreserving sperm.

Teriflunomide

Teriflunomide is another drug available for oral use in MS therapy. Teriflunomide is the active metabolite of leflunomide, and is used as a disease-modifying antirheumatic drug. By inhibiting mitochondrial dihydroorotate dehydrogenase, teriflunomide inhibits the de novo synthesis of pyrimidine and thus reduces cell proliferation. This results in a decrease in numbers of activated lymphocytes and leads to a reduction in MRI gadolinium-enhancing lesions and annualized relapse rate by nearly 30%.⁶⁹

For leflunomide, which has structural similarities to teriflunomide, a study involving 64 pregnant women with rheumatoid arthritis showed no elevated risk of congenital malformation, preterm delivery, or reduction in birth weight.⁷⁰ Although teriflunomide has shown no negative effects on fertility in animal studies, there is evidence of reproductive toxicity. The only existing data on pregnancy outcomes in humans come from the global pharmacovigilance database held by the manufacturer. In that database, 83 pregnancies in female patients and 22 pregnancies in partners of male patients were recorded.⁷¹ These pregnancies were detected during participation in teriflunomide clinical trials. The authors report 29 induced and 13 spontaneous abortions in female patients. Among partners of teriflunomide-treated males, two induced abortions and one spontaneous abortion were described. No congenital malformations were observed, and birth weight and gestational age were within the normal range.

The manufacturer recommends a reliable method of contraception during treatment with teriflunomide and as long as the plasma level is higher than 0.02 mg/L. If an unplanned pregnancy occurs during treatment, accelerated elimination of teriflunomide by cholestyramine or charcoal is strongly advised. Due to the long half-life, it might otherwise take between 8 months and 2 years after stopping teriflunomide for the plasma level to reach values below 0.02 mg/L. The extent to which this approach actually reduces the risk of an adverse pregnancy outcome is not yet known.

In MS patients who are planning pregnancy, use of teriflunomide should be discontinued and the plasma

level assessed. If necessary, the teriflunomide level can be reduced by the measures mentioned above before starting unprotected sexual intercourse. If the plasma level is below 0.02 mg/L in two measurements within an interval of 2 weeks, and a further safety interval of one and a half months is maintained thereafter, there should be no risk to the newborn.

Dimethyl fumarate

In February 2014, DMF was approved as a further oral MS drug in Europe. DMF reduces the annualized relapse rate by approximately 50% and leads to a significant decrease in contrast-enhancing lesions on MRI.⁵⁵ The manufacturer's information describes that, in animal studies, high doses of DMF led to fetal growth restriction and increased lethality, although fertility does not seem to be reduced. The outcome of 25 pregnancies in humans undergoing DMF therapy was presented at the 2013 annual meeting of the American Academy of Neurology.⁷² No increase in rates of spontaneous abortion or fetal malformation were reported. However, given that existing safety data are insufficient, DMF is not recommended for use during pregnancy.

Alemtuzumab

Alemtuzumab is a recombinant monoclonal antibody directed against CD52 on the cell surface of T and B lymphocytes. Alemtuzumab mediates immunosuppressive effects by depletion and repopulation of white blood cells. Compared with IFN- β , it leads to a significant reduction in annualized relapse rates and contrast-enhancing MRI lesions.^{73,74} With an interval of 1 year alemtuzumab is given on 5 and 3 consecutive days, respectively, followed by a mandatory safety monitoring period of 48 months. Animal pregnancy studies showed a significant reduction in the number of viable fetuses and a higher number of animals with intrauterine deaths due to administration of alemtuzumab during pregnancy. Moreover, lower weight gain during gestation was observed.

The manufacturer indicates that within 30 days after each alemtuzumab treatment cycle, serum levels were low or even not detectable. However, females of childbearing age are advised to avoid pregnancy during and 4 months after each treatment period, because alemtuzumab is known to cross the placenta barrier. Data on pregnancies occurring during clinical trials have not yet been published by the manufacturer.

Breastfeeding in MS

There is still insufficient knowledge on whether breastfeeding influences the course of MS, and postpartum relapse rate in particular. The results of several studies have been quite

controversial, in some cases showing protective effects⁷⁵⁻⁷⁷ and in other cases showing no effects.^{8,78,79} A meta-analysis of 12 studies revealed a positive effect of breastfeeding on the relapse rate, although many factors may contribute to a bias in those studies.⁸⁰ Some studies were carried out retrospectively; moreover, in some, nursing women already had a lower annualized relapse rate before pregnancy and were less frequently treated with DMD compared with patients who were not breastfeeding. In any event, the risk of postpartum relapse during lactation always has to be weighed critically against starting treatment with a DMD soon after delivery. In patients with a high risk of relapse, waiving DMD in favor of breastfeeding has to be considered carefully, whereas in patients with low disease activity it may be justifiable.

Medication for MS during lactation

None of the DMDs mentioned above has been approved for treatment of MS during lactation. Methylprednisolone is known to pass into breast milk. For this reason, many women are advised to wean their child when receiving glucocorticoids for treatment of relapses. Nevertheless, there is a tendency to continue nursing despite cortisone therapy. If an interval of 4 hours between medication and breastfeeding is maintained, this approach seems to be reasonable.³³ IFN- β and GA might be the safest DMDs to use during lactation because they have a high molecular weight and are not detectable to a relevant extent in breast milk.⁸¹ Natalizumab, fingolimod, and mitoxantrone are known to pass into breast milk and should not be used by breastfeeding women. Animal studies have shown that teriflunomide and alemtuzumab pass into breast milk; for DMF there is no information on that issue available.

Fatherhood in patients with MS

Little is known about the course and outcome of pregnancies fathered by men with MS. In 2010, the first study on pregnancy outcomes in MS fathers receiving disease-modifying therapy (DMT) was published by Hellwig et al.⁸² Compared with healthy mothers and MS mothers with and without DMT, no differences were found in birth weight and length. Recently, Lu et al published data on 202 pregnancies fathered by 141 men with MS.⁸³ There were no differences in mean birth weight and gestational age compared with fathers without MS. Bearing in mind the lack of data, it seems reasonable for male MS patients to continue DMT during the conception period. Only treatment with mitoxantrone, as mentioned above, should be stopped 6 months before pregnancy.

Conclusion

Managing MS medication is a challenge, particularly when patients are pregnant or breastfeeding. For drugs that have been available for decades, such as IFN- β and GA, there is an increasing amount of information from pregnancy registries and observational studies. For new medications, such as DMF or teriflunomide, significantly less data are available. Therefore, further documentation in pregnancy registries of (unplanned) pregnancies with in utero exposure to DMDs is urgently needed. Attending physicians need to stay informed about current findings in MS pregnancy studies to be able to provide their patients with individual counseling based on the current state of knowledge.

Degenerative Neurological and Neuromuscular Disease

Publish your work in this journal

Degenerative Neurological and Neuromuscular Disease is an international, peer-reviewed, open access journal focusing on research into degenerative neurological and neuromuscular disease, identification of therapeutic targets and the optimal use of preventative and integrated treatment interventions to achieve improved outcomes, enhanced

survival and quality of life for the patient. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/degenerative-neurological-and-neuromuscular-disease-journal>
