ABSTRACT

Background and study aims Management of post-sphincterotomy perforations is variable, with some patients managed conservatively and other requiring surgery. Fully-covered self-expanding metal stents (FCSEMs) have been used in the past, but data is limited. The aim of this study was to report the clinical characteristics and outcomes fol-

lowing placement of anchored FCSEMs for the immediate management of post-sphincterotomy perforation.

Patients and methods All patients undergoing an ERCP procedure between June 2011 and December 2015 at our institution were reviewed for post-sphincterotomy perforation. All intra-procedurally recognized perforations underwent placement of FCSEMs with flexible anchoring fins and were included in this study. Data extracted included patient demographics, indication, peri-procedural details, clinical course and long-term outcome following anchored FCSEM placement.

Results A total of 15 patients (12 females, median age-66 years) with post-sphincterotomy perforation were included. Major indications included choledocholithiasis in 9 (60%), and 5 (33.3%) patients had intra-ampullary or peri-ampullary diverticula. All patients underwent placement of FCSEM without any complication and had immediate resolution of perforation as evidenced by decrease in fluoroscopic gas and lack of contrast extravasation. None of the patients became symptomatic or needed surgery with a median 2 days of hospitalization following the procedure. Stents were removed after a median of 30.5 days and no complications were noted during follow-up after stent removal.

Conclusions Anchored FCSEMs are safe and effective for management of intra-procedurally recognized post-sphincterotomy perforations and obviates need for surgery.

Introduction

Perforation is one of the most dreaded complications of endoscopic retrograde cholangiopancreatography (ERCP), which if unrecognized or untreated is associated with a relatively high morbidity and mortality [1–4]. ERCP-related perforations are formally categorized using the Stapfer classification system which incorporates the mechanism, location and severity of perforations [5]. Among these, Stapfer type II perforations (periampullary perforations of the medial wall of the duodenum) associated with biliary or pancreatic sphincterotomy or precut sphincterotomy, represent the most frequent type of

perforation, comprising anywhere from 15% to 68% of all cases [5–7]. Post sphincterotomy perforation occurs in 0.3–1.3% of ERCP procedures with a relatively high mortality rate of 7% to 14% [1–4, 8]. Currently there is no consensus regarding management of post-sphincterotomy perforations as their incidence is very low and the clinical consequences vary enormously [9]. While some experts advocate a conservative approach based on the clinical course, others favor upfront surgical repair, given the complications associated with delayed operative intervention [10, 11]. Traditional management consists of close monitoring and the diversion of gastric, duodenal, and biliary fluid through nasogastric tubes, naso-duodenal tubes, and

endoscopic naso-biliary tubes, respectively [7]. A few reports showed the safe and effective use of metallic endoclips in the closure of sphincterotomy related duodenal perforations [10, 12, 13]. Plastic stents have been used for treatment of post-sphincterotomy perforations, but their limited diameter may fail to completely manage the underlying problem [14]. Fully-covered self-expanding metal stents (FCSEMs) have been suggested for management of post-sphincterotomy perforations, as the covered wide-caliber stent can provide complete sealing of the defect, while the stent lumen enables physiologic drainage of bile and thus prevent additional fluid leakage. Data regarding the latter approach, is restricted to a few patients mostly after delayed presentation [14, 15]. Our hypothesis is that immediate short-term stenting of post-sphincterotomy perforations with FCSEMs when recognized during the initial ERCP procedure facilitates quicker recovery and obviates need for surgery. The aim of our study was to report the outcomes of the use of an anchored nitinol fully-covered self-expanding metal stent for management of these post-sphincterotomy perforations.

Patients and methods

All patients who underwent ERCP at our institution between June 2011 and December 2015 were reviewed for post-sphincterotomy perforation. All endoscopic complications were collected prospectively during the interval by an online reporting system, with every member of the endoscopy faculty, consult service attending, and nursing staff having access to enter complications. All intra-procedural perforations underwent placement of a biliary FCSEM with flexible anchoring fin and were included in this study. Demographic characteristics of the patients, indication for the procedure, findings at ERCP, endoscopic and radiographic findings of the sphincterotomy related perforation, post-procedure course including SIRS following procedure (fever >100.4 , heart rate >90 , respiratory rate >20 or $\text{Paco}_2 <32$ mmHg or WBC $>12,000$ or <4000), length of post-procedural hospital stay, and timing of the subsequent ERCP were retrospectively extracted. Presence or absence of a gallbladder and the relationship of the anchored FCSEM to the cystic take-off was noted. In addition, development of other ERCP-related adverse events (AEs) were classified according to the consensus guidelines [16].

Definitions

Endoscopic sphincterotomy perforation was defined as presence of free intraperitoneal or retroperitoneal air visualized fluoroscopically during or immediately after sphincterotomy, with or without obvious full-thickness defect above the upper margin of the bile duct, and/or extraluminal contrast extravasation at the sphincterotomy site.

Procedural details

All ERCP procedures were performed under general anesthesia by experienced endoscopists (MA, RA, MF and SA) who had each performed >2500 procedures. Standard video duodenoscopes (TJF-160/180 series, Olympus America Inc., Center Val-

ley, Pennsylvania, USA) were utilized with carbon dioxide (CO_2) for insufflation. All sphincterotomies were performed using the new generation microprocessor-controlled electro-surgical generator (ERBE, ERBE USA). If there was a strong suspicion of sphincterotomy-related perforation using the above definition, they were immediately treated by placement of biliary fully covered self-expanding metal stent. In addition, if the distal bile duct was felt to be sufficiently small caliber to risk compression of the pancreatic orifice by the FCSEMS or if the patient was considered at moderate to high risk of post-ERCP pancreatitis, a pancreatic stent was prophylactically placed prior to deployment of the FCSEMS. Pancreatic stents used were 4Fr \times 11 cm soft material unflanged stents (Freeman-Hobbs stent, Hobbs Medical) or 5Fr \times 3 cm Sofflex stents (Cook Medical, Winston-Salem, NC). Biliary FCSEMS were 10-mm luminal diameter ranging from 4 cm to 8 cm in length with anti-migratory properties involving anchoring fins (Viabil, Conmed, Utica, New York, United States) and were deployed in a transpapillary fashion (as shown in ► **Video 1**). When the gallbladder was in situ, FCSEMSs were placed below the cystic-duct insertion or FCSEMSs with upstream fenestrations were used to avoid cystic duct obstruction. All patients were admitted overnight for observation. All were scheduled for second ERCP during which the FCSEMSs were removed with either a rat-toothed forceps or cold snare. The stent was usually withdrawn through the instrument channel or by withdrawing the duodenoscope with the stent in tandem. After stent removal, an occlusion cholangiogram was performed to confirm the resolution of the post-sphincterotomy perforation. Long-term follow-up was performed by reviewing clinical notes during subsequent clinic visits and available laboratory results and imaging performed weeks to months after stent removal.

► **Video 1** Video illustrates a case of post-sphincterotomy perforation recognized during the procedure and managed successfully with the placement of anchored FCSEMS.

► **Table 1** Patient demographics and baseline characteristics.

No of patients included	15
Sex (male/female)	3/12
Age median (range) in years	66 (20–96)
White	12 (80%)
ASA physical status	
ASA I	1 (6.7%)
ASA II	10 (66.7%)
ASA III	4 (26.7%)
Indication for ERCP	
Bile duct stone	9 (60%)
Suspected SOD	4 (26.7%)
Benign biliary stricture	1 (6.7%)
Post-cholecystectomy leak	1 (6.7%)
Anomalous anatomy	
Periampullary diverticulum	5 (33.3%)
Roux-en-Y gastric bypass	1 (6.7%)
Type of sphincterotomy (initial/extension/pre-cut)	13/2/1
ERCP, endoscopic retrograde cholangiopancreatography; SOD, sphincter of Oddi dysfunction	

Results

A total of 4860 ERCP procedures, including 1784 initial or extension biliary sphincterotomies were performed during the study period. During the study period, fifteen patients (females 12 [80%], male 3 [20%] and median age 66 years) were recognized with post-sphincterotomy perforations at the time of ERCP. None of the 1784 sphincterotomy patients had delayed recognition of perforation. Most patients were ASA II status, though some were ASA I and III. The baseline characteristics of these patients have been summarized in ► **Table 1**.

In patients with perforations, the most common indication for ERCP was bile duct stone extraction (60%), followed by sphincter of Oddi dysfunction (26.7%) and other indications (13%). Extension of previous sphincterotomy was performed in 2 of the 15 patients (13.3%). A difficult or failed cannulation by standard technique was encountered in 3 (20%) of the patients with one patient needing pre-cut (free-hand needle-knife) sphincterotomy and two patients needing EUS guided rendezvous for access to bile duct. Peri or intra-diverticular papillae were encountered in 5 (33.3%) of the patients. Lengths of the stent deployed were 4 cm (2 patients), 6 cm (10 patients) and 8 cm (3 patients).

The median length of stay in the entire cohort was 2 days. SIRS response was witnessed in only 1 patient (6.7%) within 48 hours after the procedure and no patients developed sepsis related complications or post ERCP pancreatitis or cholecystitis (as shown in ► **Table 2**). The stents were left for a median dura-

► **Table 2** Procedure outcomes following placement of anchored FCSEM.

Procedure-related adverse events, n (%)	
Post-ERCP pancreatitis	0
Cholangitis	0
Post-ERCP cholecystitis	0
Death	0
Median (range) length of hospital stay in days	2 (0–10)
Median (range) duration in days of stent placement	30.5 (14–45)
Median follow-up in days after stent removal	150

tion of 30.5 days (range 14 to 45 days) and were all retrieved without any complications such as fracture, stent migration or tissue ingrowth. The median follow-up after stent removal was 150 days. None of the patients developed any late complications after stent removal.

Discussion

ERCP has evolved from a diagnostic to a therapeutic modality for biliary and pancreatic disease. The increase in volume and complexity of these procedures has led to an increase in number and spectrum of complications [8]. Post-sphincterotomy perforations caused by extension of a sphincterotomy incision beyond the intramural portion of the bile or pancreatic duct is classically associated with high morbidity and mortality. Although some experts favor conservative management, a recent systematic review of 11 studies showed that after initial non-surgical management, surgery was needed in 29/137 (21%) of patients with Stapfer type II perforation with a mortality of 38% in those undergoing delayed surgery [17]. It was reasoned that operative interventions for perforations, when delayed, become technically more challenging because of adhesions and loss of tissue planes and was associated with higher mortality [11, 17, 18]. Thus, optimal management for post sphincterotomy perforations remains contentious. If the appropriate expertise and equipment is available, endoscopic closure has been shown to obviate surgical intervention [19]. Endoscopic closure using hemostatic endoscopic clips or an over-the-scope clipping device has been described [10, 12, 13]. However, deployment of these clips to seal medial wall perforation is technically challenging with the duodenoscope [20]. Moreover, over-the-scope clips cannot be reproducibly applied because of angulation and difficult access with a potential risk for closing the ampullary orifice [20]. Placement of stents across the sphincterotomy site results in mechanical occlusion of the perforation site facilitating free flow of bile into the duodenum, thus minimizing the risk of bacterial translocation and peritonitis [17]. FCSEMs are preferred over plastic stents or naso-biliary drains since they provide larger caliber for complete sealing of the perforation defect and the stent lumen may facilitate physiologic drainage of bile to prevent additional fluid leakage

[17]. In our study, we demonstrated that the immediate intra-procedural deployment of anchored FCSEMs for a short term completely obviates the need for surgery in all the patients and was associated with no added morbidity or mortality.

During our study period (June 2011 to December 2015), a total of 4860 ERCP procedures were performed, with 1784 (initial or extension) sphincterotomies performed. Post sphincterotomy perforations were recognized intra-operatively in 15 patients (0.8%) and all were managed with placement of an anchored FCSEM. Difficult cannulation was encountered in 3 of the 15 patients (20%) with 2 of the patients needing EUS-guided rendezvous procedure to obtain biliary access and one patient needing pre-cut traction sphincterotomy, the latter a recognized risk factor for post sphincterotomy perforation [1, 6, 8, 21]. The presence of peri or intra-diverticular papilla was again shown to be a significant risk factor for perforation, which is consistent with prior studies [8]. Type 2 sphincter of Oddi dysfunction was the indication in 26.7% of the ERCP procedures and itself is a recognized risk factor for Stapfer type II perforation as the goal is complete ablation of the sphincter muscle [21]. Another observation was that 4 (26.6%) of our patients had concomitant post sphincterotomy bleeding, which was managed by immediate subepithelial injection of (1:10,000) epinephrine prior to stent deployment. This is consistent with another Turkish study, which reported an incidence of 15% of sphincterotomy related bleeding. However, none of our patients developed post ERCP pancreatitis in contrast to the 15% reported in the same study. This can be attributed to our placement of prophylactic pancreatic duct stents in eleven (73.3%) of our patients along with adjuvant rectal indomethacin administration in all appropriate patients. Although 6/15 (40%) had a gallbladder in situ at the time of placement of the FCSEM, none developed cholecystitis. This was not surprising as FCSEMs with upstream fenestrations were placed in these patients below the cystic duct insertion to specifically avoid cystic duct obstruction.

We believe early recognition of the post-sphincterotomy perforation, use of CO₂ for insufflation and prompt management with fully-covered stent placement were critical for our successful outcomes. It can be argued that these patients could have had a similar outcome if subjected to conservative management. However, given the existing literature and our patient population with a median age of 66 years, 14 of the 15 patients having multiple comorbid conditions (ASA II and III) and the unpredictable course of conservative management, we thought it prudent to place these stents during the procedure. Patients resumed oral feeds and were discharged rapidly from the hospital, and FCSEM removal, which occurred after a median duration of 30.5 days, was performed on an outpatient basis. The cost of these stents should be weighed against the risk of prolonged hospitalization and possible intensive care requirements and potential subsequent need for surgery. There were no complications related to insertion or removal of the FCSEMs. Stent migration or tissue hyperplasia noted in other related studies was not seen in our series and none of our stents fractured [14, 15]. The purpose of the anchored FCSEMs is to provide the radial force to occlude the perforation site, allowing

expedited healing and the anchoring fins prevented migration of the stent. The potential complication of stent related sludge formation and reflux of gastroduodenal contents should prompt close follow up and removal of FCSEMs in a timely fashion.

Limitations of the study include the retrospective nature of the study design and lack of a control arm. As this is our practice for management of all sphincterotomy perforation and we were exploring the role of immediate stent placement, a control arm was not feasible. The sample size for our study was relatively small, but considering the 0.3% to 1% incidence of ERCP-related perforations, with only half being represented by post-sphincterotomy perforation, our sample size is reasonable. Moreover, this is the largest study to date investigating the role of intraprocedural anchored FCSEMs placement for the management of this complication.

Conclusion

In conclusion, our study shows that post-sphincterotomy perforations when promptly recognized and immediately managed with placement of anchored FCSEMs prevented significant complications such as SIRS, or development of major extraluminal complications. There was no need for surgery or other invasive interventions and outcomes were acceptable. Given the low incidence of post-ERCP perforations, our findings need to be further validated through multicenter, prospective studies, before recommending routine placement of these stents to manage post-sphincterotomy perforations.
