Abstract

Background: Examining tumor KRAS/NRAS/BRAF/PIK3CA status in metastatic colorectal cancer (mCRC) is essential for treatment selection and prognosis evaluation. Cell-free DNA (cfDNA) in plasma is a feasible source for tumor gene analysis.

Methods: In this study, we recruited mCRC patients and analyzed their KRAS/NRAS/BRAF/PIK3CA status in cfDNA using two platforms, next-generation sequencing (NGS) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF). The performance between the two platforms and the concordance rate between cfDNA and tissue were analyzed. The relationship between cfDNA-related variables and clinical variables was also assessed. Tumor mutations in cfDNA from patients receiving continuous treatments were monitored in the follow-ups.

Results: Next-generation sequencing and MALDI-TOF had similar specificity (100.0% vs. 99.3%) and negative predictive value (99.9% vs. 99.4%), whereas NGS had higher sensitivity (97.1% vs. 85.3% of MALDI-TOF) and positive predictive value (100% vs. 82.9% of MALDI-TOF). The overall concordance rate of NGS and MALDI-TOF was 98.6%. For the reportable types of mutations in both cfDNA and tissue, the concordance rate was 96.1%. Among 28 tissue-positive patients, the allele frequencies of tumor mutations in cfDNA were higher in patients with primary tumor burden ($p = 0.0141$). Both CEA and CA 19-9 were positively correlated with cfDNA

and Technology Commission of Shanghai Municipality (21YF1440200).

concentration ($r = 0.3278$ and $r = 0.3992$). The allele frequencies of tumor mutations changed with disease progression.

Conclusions: Next-generation sequencing showed slightly better performance in detecting cfDNA mutations and was more suitable for clinical practice. cfDNA-related variables reflected the tumor status and showed a promising potential in monitoring disease progression.

1 | INTRODUCTION

Colorectal cancer (CRC) is the third most common malignancy worldwide.^{1–3} The mutations of driver genes, including KRAS, NRAS, BRAF and PIK3CA, contribute to tumorigenesis of CRC.^{4,5} It has been reported that mutation frequencies of KRAS, NRAS, BRAF and PIK3CA in CRC are 35.7%–45.4%, 3.9%–6.3%, 3.1%–7.1%, and 3.5%–16.1%, respectively.^{2,6} Meanwhile, these mutations may suppress the response to targeted treatments for metastatic colorectal cancer (mCRC), like epidermal growth factor receptor (EGFR) targeted monoclonal antibodies (mAbs), cetuximab and panitumumab.^{7–9} Therefore, it is critically essential to assess the mutation status of these genes in patients.³

Tumor tissue is a suitable source for mutation detection in cancer patients.^{10,11} However, it is not always available during cancer management, due to the difficulty and invasion of tissue biopsy. An alternative approach is liquid biopsy including cell-free DNA (cfDNA) and RNA.^{12,13} A fraction of cfDNA originates from tumors in cancer patients, referred as circulating tumor DNA (ctDNA), and may carry the same genetic mutations as those of a primary tumor.¹² ctDNA has shown a prognostic value comparable to tissue biopsy in the management of non-small cell lung cancer (NSCLC) and CRC.^{1,3,10,14}

A number of platforms are available for cfDNA analysis and classified into two major groups, single-spot detection and broad-coverage profiling.^{10,15,16} Initially, only a few driver gene mutations with a prognostic value were known and single-spot detection platform, including droplet digital polymerase chain reaction (ddPCR) and amplification refractory mutation system (ARMS), was sufficient for clinical practice.¹⁵ Gradually an increasing number of genes and mutations have been found of clinical importance, raising the demand for broad-coverage profiling. Nowadays there are already some commercially available kits for broad-coverage profiling of cfDNA on NGS or MALDI-TOF platform.¹⁷

Here, in this study, we recruited mCRC patients and performed a prospective study to evaluate the capacities of two platforms, NGS and MALDI-TOF, in detecting tumor mutations from plasma cfDNA. We also compared the cfDNA results with tissue results to assess their concordance. Furthermore, we analyzed the correlation of cfDNA-related variables with clinical variables and monitored them in the follow-ups. The findings in our study may help better

understand the potential clinical value of cfDNA analysis and determine the suitable platform in clinical practice.

2 | MATERIALS AND METHODS

2.1 | Patient enrollment

This prospective study recruited mCRC patients receiving treatments at the department of medical oncology, Zhongshan Hospital from June 2016 to December 2017 (Figure 1). All patients enrolled should be pathologically confirmed at stage IV, with known KRAS, NRAS, BRAF and PIK3CA status of the tissue, which was tested by ARMS according to routine procedures. In addition, the patients should successfully complete the cfDNA analysis by both NGS and MALDI-TOF. This study was conducted in accordance with the Declaration of Helsinki principles and was approved by the Institutional Review Board of Zhongshan Hospital. All subjects gave written informed consent.

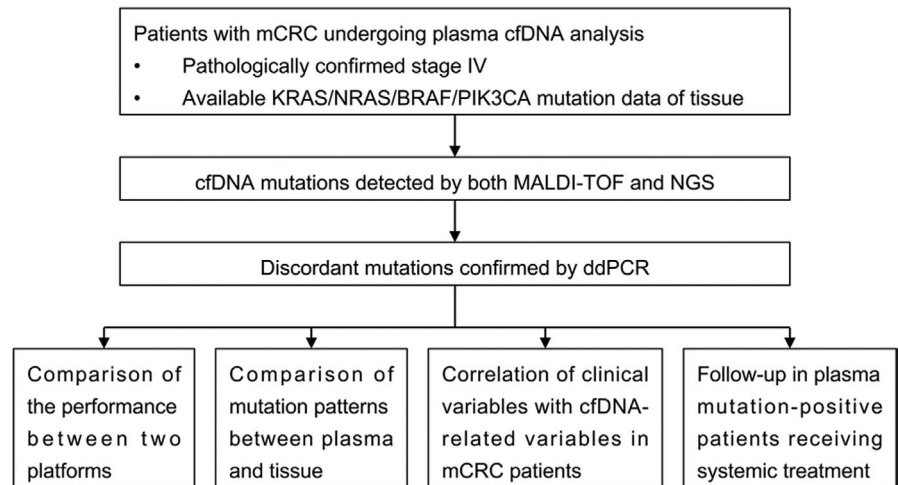

2.2 | Sample collection and DNA extraction

The sample collection and DNA extraction were described previously.¹ Briefly, a total of 20 ml of venous blood was collected from each patient and the plasma was separated. cfDNA from 8.0 ml of plasma was extracted, quantified and qualified using QIAamp Circulating Nucleic Acid Kit (QIAGEN, 55114), Qubit fluorometer 3.0 (Life Technologies, Grand Island, NY) and 2100 bioanalyzer (Technologies, Palo Alto, CA). Extracted cfDNA was stored at -80°C until use.

2.3 | Mutation profiling by NGS

Plasma cfDNA was subjected to amplicon-based Firefly CRC panel (Accu-Kit CRC01, AccuraGen, Shanghai, China), comprising a total of 216 hotspots in exon 2, 3, and 4 of KRAS, exon 2 and 3 of NRAS, exon 9 and 20 of PIK3CA and exon 15 of BRAF, to construct the DNA library (Table S1). DNA libraries were sequenced on an Illumina

FIGURE 1 The flowchart of the study. The mCRC patients were recruited and their plasma cfDNA was analyzed

MiSeq Dx (Illumina, San Diego, CA, USA) and sequencing data were analyzed using CometScope software (AccuraGen, Shanghai, China). The limit of detection of Firefly NGS was at an allele frequency of 0.2% for 20 ng cfDNA as previous reported.¹

2.4 | Mutation profiling by MALDI-TOF

Plasma cfDNA analysis was also carried out by MALDI-TOF using the UltraSEEK Panel (Agena Bioscience, San Diego, CA), comprising a total of 97 hotspots in exon 2, 3, and 4 of KRAS and NRAS, exon 9 and 20 of PIK3CA, exon 14 and 15 of BRAF and exon 12 of EGFR (Table S2). Briefly, UltraSEEK analysis consisted of standard multiplex PCR, a mutation-specific single-base extension reaction using chain terminators labeled with a moiety, and characterization using MALDI-TOF. The mutational genotypes were identified using the supporting Typer software and automated UltraSEEK Report software.

2.5 | Validation of discordant results using ddPCR

The results for the overlapped hotspot mutations between NGS and MALDI-TOF underwent a comparative analysis (Table S3). Confirmatory tests for the discrepancies between NGS and MALDI-TOF were performed on a QX200 ddPCR system using commercial ddPCR kits (BIO-RAD, Hercules, CA, USA). The results were analyzed using Quantasoft v.1.7 software. The limit of detection of ddPCR was at an allele frequency of 0.1% for 10 ng cfDNA.

2.6 | Comparison between NGS and MALDI-TOF on cfDNA analysis

Hotspot mutations confirmed by at least two of the three platforms (NGS, MALDI-TOF and ddPCR) were defined as true. The sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated by comparing the results of either platform (NGS and MALDI-TOF) with true results.

2.7 | Comparison between plasma cfDNA and tissue on the tumor mutations

The true results of cfDNA were compared with the tissue results (Table S4). The concordance rate among results reported in both cfDNA and tissue was calculated. The data from tissue, cfDNA and the Cancer Genome Atlas (TCGA) database were used to assess the proportions of mCRC patients carrying different mutated genes.

2.8 | Correlation between cfDNA-related variables and clinical variables

For the patients with mutations in tumor tissue, the allele frequencies of tumor mutations in cfDNA were compared between patient groups with and without tumor burden at primary site. The correlation between plasma cfDNA concentration and primary tumor burden, and serum biomarkers including carcinoembryonic antigen (CEA), carbohydrate antigen (CA 19-9) and carbohydrate antigen 125 (CA 125), were also evaluated.

2.9 | Follow-ups of patients receiving continuous treatments

For patients that had tumor mutations in tissue and received continuous treatments at Zhongshan Hospital, their cfDNA (by NGS) and serum biomarker (CEA) were tested in the follow-ups and their treatment responses were monitored using computed tomography (CT) scan.

2.10 | Statistical analysis

All the analyses were performed on GraphPad Prism software (Version 8.0.1, San Diego, CA). The Mann-Whitney *U* test and Fisher's exact test were used for non-Gaussian and categorical

observation of stable disease by CT scan showed the effectiveness of new therapeutic regimen.

Patient CRC2-23 was diagnosed as colon cancer with liver metastasis. A KRAS exon 4 mutation was identified in tissue biopsy. Four cycles of mFOLFOX6 were administered since November 2017 and a decrease of mutant allele frequency (KRAS A146T) was observed (Figure 5B and Table S6). After stable disease was confirmed

by CT scan, the primary tumor and liver metastasis were removed. After surgery, plasma KRAS A146T mutation was undetectable. Although the patient received subsequent adjuvant chemotherapy, a fluctuation of the tumor mutations in cfDNA occurred and imaging showed liver relapse and lung progression in May 2017.

Patient CRC2-25 underwent colonoscopy in November 2017, which showed colon malignant tumor. Positron emission tomography/

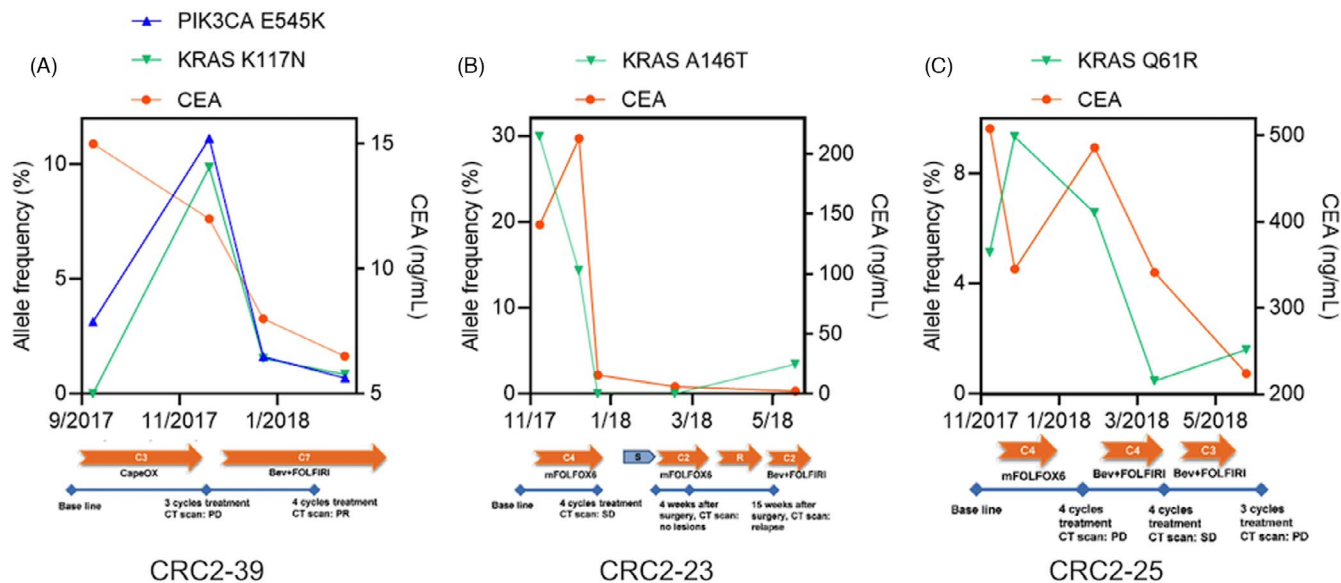

FIGURE 5 Follow-up of patients receiving continuous treatments. Mutation allele frequencies and CEA in cfDNA mutation-positive patients, CRC2-39 (A), patient CRC2-23 (B) and patient CRC2-25 (C), were recorded during treatments, respectively

TABLE 2 Advantages and disadvantages of the three platforms

Platform	Advantage	Disadvantage
NGS	<ul style="list-style-type: none"> • Multiplex (>200 hotspots in one assay) • Higher sensitivity (~0.2%) and accuracy 	<ul style="list-style-type: none"> • Long turn-around-time (at least 3 days) • Complex procedure • Various data analysis pipelines among labs
MALDI-TOF	<ul style="list-style-type: none"> • Multiplex (100–200 hotspots in one assay) • Medium turn-around-time (2d) 	<ul style="list-style-type: none"> • Limited capacity to distinguish the signal from noise • Low accuracy
ddPCR	<ul style="list-style-type: none"> • Short turn-around-time (4 h–1 day) • Highest sensitivity (~0.1%) and accuracy • Gold standard 	<ul style="list-style-type: none"> • Limited amount of target mutations per assay

CT suggested multiple liver metastases and implantation metastases at the abdomen. A KRAS exon 3 mutation was detected in the surgical sample. The mutant allele frequency (KRAS Q61R) increased during mFOLFOX6 treatment and a CT scan showed progression of liver metastases by the end of four-cycle mFOLFOX6 treatment (Figure 5C and Table S6). However, allele frequency reduced after another 4 cycles of bevacizumab + FOLFIRI and CT scan suggested stable disease. However, subsequent 3 cycles of treatments ended up with a rise of allele frequency and CT images indicating progressive disease.

4 | DISCUSSION

The effectiveness of targeted drugs is raising the awareness about the importance of molecular typing of tumor.^{6,9} Considering the tumor accumulate mutations all the time, the demand of molecular typing is always urgent during cancer management. Liquid biopsy, especially ctDNA analysis, meets the real-time examining requirement and attracts the attention of clinicians.^{10,12} Several platforms and assays have been developed to analyze tumor mutations in

cfDNA.¹⁸ Among these platforms, NGS and MALDI-TOF offer cost-effective broad-coverage profiling.

In this prospective study, we compared two commercially available assays, amplicon-based Firefly CRC panel and UltraSEEK Panel, on corresponding measuring systems, Illumina NGS and Agena MALDI-TOF, in detecting tumor mutations in cfDNA from mCRC patients. Although the overall concordance rate was high, the MALDI-TOF assay showed its shortage in accurately detecting the complicated hotspots and newly discovered mutations (Figure 2). NGS interrogates more targets (>200 hotspots) within one assay than MALDI-TOF. The commercial NGS assay reports the exact nucleotide sequence with high sensitivity (~0.2%) and accuracy. However, MALDI-TOF reports only the existence of a mutation signal and the capacity to distinguish the signal from noise is limited. The commercial MALDI-TOF assay has to amplify the mutation signal in addition, raising strict requirements for primer design. This may explain the limitation the MALDI-TOF assay suffered in this study. ddPCR considered as gold standard, is useful for detection of specific known variants, at very low level (~0.1%), mainly for validation and serial monitoring (Table 2).

Since the tumor releases its DNA into plasma, cfDNA may reflect the mutational status of tumor tissue. At single-reportable-result level, cfDNA and tissue had a high concordance rate (Figure 3). Considering the purpose of cfDNA analysis is to report the positive incidence of tumor mutation, the concordance rate at single-patient level was also analyzed in tissue-positive patients. 23 of 28 patients were also cfDNA-positive, with a concordance rate of 82.1%, suggesting that cfDNA is a promising source to monitor tumor mutations in cancer management of mCRC. Moreover, the comparison with TCGA database indicates that, for both cfDNA and tissue, broad-coverage profiling is a better option in characterizing tumor mutation status (Figure 3). These findings are consistent with previous works on non-small-cell lung cancer (NSCLC), extending the knowledge on cfDNA.^{16,17}

cfDNA-related variables showed potential values in monitoring tumor progression of mCRC. The allele frequencies of tumor mutations significantly reduced in patients without primary tumor burden (Figure 4). Previous studies on NSCLC suggested that ctDNA detection can be utilized in monitoring treatment response.¹⁹ In this study, allele frequencies of tumor mutations also responded to treatment and acted earlier than serum biomarker (Figure 5). Besides, the plasma cfDNA concentration had weak association with serum biomarker, showing additional potential in clinical application. A combination of allele frequency and cfDNA concentration is worthy of further studies.
