## ABSTRACT

Metal-organic framework (MOF) derived porous Fe<sub>3</sub>O<sub>4</sub>/C powders were applied for absorption of microwaves in the frequency range of 1–18 GHz. The effects of the polyvinylpyrrolidone (PVP) additive on the synthesis of MIL101-(Fe) precursor were studied by various characterization methods. By adding PVP, the impure hematite phase ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) with magnetite phase (Fe<sub>3</sub>O<sub>4</sub>) was disappeared and the particular morphology was transformed to the porous rod-like, leading to the increase of specific surface area from 150 to 282 m<sup>2</sup>/g. Furthermore, the saturation magnetization (Ms) of Fe<sub>3</sub>O<sub>4</sub>/C powders reached a maximum value of 47 emu/g at a proper amount of PVP. A thin absorber (2.6 mm) made of 50 wt% Fe<sub>3</sub>O<sub>4</sub>/C powders and 50 wt % paraffine absorbed the whole of X frequency band (8–12 GHz) with a minimum reflection loss of –20 dB at a matching frequency of 10 GHz. Adjusting the permittivity and permeability parameters of the Fe<sub>3</sub>O<sub>4</sub>/C powders via adding PVP was responsible for their better microwave absorption performance.

## 1. Introduction

Fifth-generation (5G) networks and wireless telecommunication technologies are rapidly developing for their higher transmission speed and network capacity [1–3]. However, their electromagnetic waves (EMWs) are detrimental to human health and can interfere the performance of electronic devices, demanding the microwave absorber materials (MAMs) for shielding against EMWs. The energy of EMWs can be converted into heat using the magnetic and dielectric MAMs [4,5]. Several MAMs such as graphene, TiO<sub>2</sub>, SiO<sub>2</sub>, SiC, ZnO, CoFe<sub>2</sub>O<sub>4</sub>, Fe<sub>3</sub>O<sub>4</sub>, and BaFe<sub>12</sub>O<sub>19</sub>, are developed for electromagnetic interference shielding applications [6–8]. The absorption performance of various MAMs is usually characterized based on absorption capacity, effective absorption bandwidth (EAB), and matching thickness. A broad EAB at a small matching thickness is suitable for practical applications [9–11].

Magnetic spinel ferrite (MFe<sub>2</sub>O<sub>4</sub>, M = Fe, Co, Ni, Mn, Zn) and hexagonal ferrite (MFe<sub>12</sub>O<sub>19</sub>, M = Sr, Ba, Pb) are considered as high-performance MAMs due to their dielectric and magnetic nature [12–14]. Among them, magnetite (FeFe<sub>2</sub>O<sub>4</sub>) has several physico-chemical properties such as high saturation magnetization, high permeability, facile synthesis, and low cost, making it as a notable MAM [15,16]. The spinel structure of Fe<sub>3</sub>O<sub>4</sub> is based on a face-centered cubic arrangement of 32 oxygen ions in which the Fe<sup>3+</sup> and M<sup>2+</sup> cations are distributed between 16 octahedral [B] and 8 tetrahedral (A) sites [17]. The magnetic and dielectric properties of the Fe<sub>3</sub>O<sub>4</sub> powders are mainly tunable by adjusting their phase purity, microstructure, and the cations distribution between (A) and [B] sites through synthesis method [18,19].

Generally, the Fe<sub>3</sub>O<sub>4</sub> nanoparticles are synthesized by precipitation method in which the ferric and ferro chlorides are

simultaneously precipitated by adding NaOH agent. However, the low temperature of the precipitation method results in the lower magnetic properties. Therefore, the high-temperature synthesis methods such as solvothermal, thermal decomposition, and solution combustion have been applied for preparing the  $\text{Fe}_3\text{O}_4$  nanoparticles with high magnetic properties [20–25]. The metal-organic framework (MOF) approach has versatility and tunability in the morphology, pore size, and pore volume of the  $\text{Fe}_3\text{O}_4$  powders [24]. In the MOF approach, the metal precursors are coordinated by organic ligands such as terephthalic acid, trimesic acid, 1,4-benzene dicarboxylate, etc. in organic solvents to form 1D, 2D, and 3D open structures. The MOF precursor can be then pyrolyzed to the porous materials by exhausting the gaseous products [26–28]. The various MOF-derived materials with high specific surface areas are applied in energy storage and conversion systems, gas sensing, and absorption of EM waves [29–31]. The textural properties of MOF-derived materials are dependent on the synthesis conditions such as the amount and type of ligand and solvent, organic additives, etc. [32,33].

In this work, the effects of the polyvinylpyrrolidone (PVP) additive were studied on the synthesis of MIL101-(Fe) as a precursor for preparing the  $\text{Fe}_3\text{O}_4$  nanoparticles for microwave absorption applications. The morphology was transformed from particular to rod-like with sheetlike building blocks by adding PVP. The saturation magnetization ( $M_s$ ) reached a maximum value of 47 emu/g using a proper amount of PVP. The higher  $M_s$  value, the higher permeability. The higher microwave absorption performance was attributed to the better impedance matching caused by a proper combination of permittivity and permeability parameters.

## 2. Experimental procedures

### 2.1. Materials

Terephthalic acid ( $\text{H}_2\text{BDC}$ ) ( $\text{C}_6\text{H}_4(\text{COOH})_2$ ), ferric chloride hexahydrate ( $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ), PVP ( $(\text{C}_6\text{H}_9\text{NO})_n$ , K-30), and N, N-dimethylformamide (DMF) were provided from Merck Chemical Co.

### 2.2. Synthesis of $\text{Fe}_3\text{O}_4$ nanoparticles

The MIL101-(Fe) was prepared by a solvothermal process [34]. Firstly, 1.705 g  $\text{H}_2\text{BDC}$  and 3.581 g  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$  were completely dissolved in 90.0 mL DMF by magnetic stirring. The various amounts of PVP (1.47 and 2.94 g) were also added to the precursor solution which was then treated in a 100 mL-Teflon-lined stainless reactor at 110 °C for 20 h. The obtained brown precipitates were collected and dried at 60 °C for 3 h. The MIL-101(Fe) powders were transformed into the  $\text{Fe}_3\text{O}_4$  nanoparticles by pyrolyzing at 650 °C for 2 h under Ar atmosphere with a heating rate of 5 °C  $\text{min}^{-1}$ . The  $\text{Fe}_3\text{O}_4$  nanoparticles were coded as P0, P1, and P2 based on the PVP contents.

### 2.3. Materials characterization

The MOF-derived  $\text{Fe}_3\text{O}_4$  powders were structurally analyzed on a D8 ADVANCE X-ray diffractometer (Bruker, Japan). The  $\text{CuK}\alpha$  ( $\lambda = 1.540 \text{ \AA}$ ) irradiation was generated at 30 kV and 10 mA for obtaining the diffraction pattern. The diffraction range ( $2\theta = 10^\circ\text{--}80^\circ$ ) was scanned in a rate of  $0.04^\circ/0.5 \text{ s}$ . An X-ray photoelectron spectroscopy (XPS) (BESTEC, EA 10, Germany) was applied for

Fig. 1. XRD patterns of (a) MIL-101(Fe) and (b) MOF-derived  $\text{Fe}_3\text{O}_4$  powders versus PVP contents.

characterizing the valence state of the Fe, O, and C elements in the surface of  $\text{Fe}_3\text{O}_4$  nanoparticles. The microstructure was observed using VEGA II scanning electron microscopy (TESCAN, Czech Republic). A Tristar 3000 instrument (Micromeritics, USA) was applied for measuring the nitrogen ad/desorption isotherms on the degassed powders at 250°C for 5 h. The magnetic properties of the  $\text{Fe}_3\text{O}_4$  powders were determined on a vibrating sample magnetometer (Meghnatis Daghigh Kavir Co., Iran) at room temperature.

The values of relative permittivity ( $\epsilon_r = \epsilon' - j\epsilon''$ ) and permeability ( $\mu_r = \mu' - j\mu''$ ) of the toroidal-shaped coaxial sample ( $\psi_{\text{out}} = 7.0$  mm and  $\psi_{\text{in}} = 3.04$  mm) were measured on a vector network analyzer (VNA) (Agilent/HP 8722 ES). According to ASTM D7449 standard, the  $\text{Fe}_3\text{O}_4$  powders were mixed with paraffine (50 wt%) in toluene solvent under sonication. Then the paste was molded and dried at 80 °C in an oven.

### 3. Results and discussion

XRD patterns of the MIL-101(Fe) and MOF-derived  $\text{Fe}_3\text{O}_4$  powders versus PVP contents are shown in Fig. 1a. The reflections of MIL-101 are in accordance with the reported patterns for MIL structure which is composed of metal nodes ( $\text{Fe}^{3+}$ ) in carboxylate trimeric clusters [35]. The structure of MIL-101 are independent of PVP additives (Fig. 1a), confirming its high purity. After pyrolyzing, the P0 powders have the reflections of (111), (022), (311), (004), (224), (115), and (044) which are related to the spinel structure of magnetite phase with space group of Fd3m (PDF2#01-075-0449). Furthermore, there are the reflections of  $\alpha\text{-Fe}_2\text{O}_3$  phase (PDF2#00-039-1346) in the P0 sample which are disappeared by adding the PVP. The ferric ( $\text{Fe}^{3+}$ ) cations are coordinated through oxygen atoms of carboxylic groups which can be decomposed into the hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) phase during calcination at high temperatures. Burning the organic framework releases the CO and  $\text{H}_2$  gases which reduce  $\alpha\text{-Fe}_2\text{O}_3$  to  $\text{Fe}_3\text{O}_4$ . Burning the PVP molecules liberated a large amount of gaseous products such as CO and  $\text{H}_2$ , benefitting for the complete reduction of  $\alpha\text{-Fe}_2\text{O}_3$  to  $\text{Fe}_3\text{O}_4$ . The crystallite size and lattice strain were determined from the peak broadening in which the crystallite size decreases from 45 to 33 nm, while the lattice strain increases from  $-0.1$  to  $+0.2$  % by the increase of PVP, indicating their lower crystallinity.

The full XPS spectrum of the P1 sample (Fig. 2a) shows three typical peaks of C1s (284 eV), O1s (531 eV), and Fe2p (711 eV), suggesting the presence of C, O, and Fe elements. The high-resolution XPS spectra show further elemental detailed information. There are two peaks of 711.1 eV and 724.6 eV in the high-resolution Fe2p spectrum (Fig. 2b), respectively corresponding to  $\text{Fe}2p_{3/2}$  and  $\text{Fe}2p_{1/2}$  on account of the spin-orbit coupling [36]. The  $\text{Fe}^{3+}$  species has  $\text{Fe}2p_{3/2}$  (712.1 eV) and  $\text{Fe}2p_{1/2}$  (725.4 eV) components with a satellite peak at 716.7 eV [37]. However, a pair of  $\text{Fe}2p_{3/2}$  (711.5 eV) and  $\text{Fe}2p_{1/2}$  (723.8 eV) components with a satellite peak at 732.7 eV are related to the  $\text{Fe}^{2+}$  species [38]. As shown in the O1s spectrum in Fig. 2c, the two peaks at 530.28 and 528.92 eV are respectively corresponded to Fe–O–C and Fe–O species [39], meaning that there is some residual carbon on the  $\text{Fe}_3\text{O}_4$  nanoparticles.

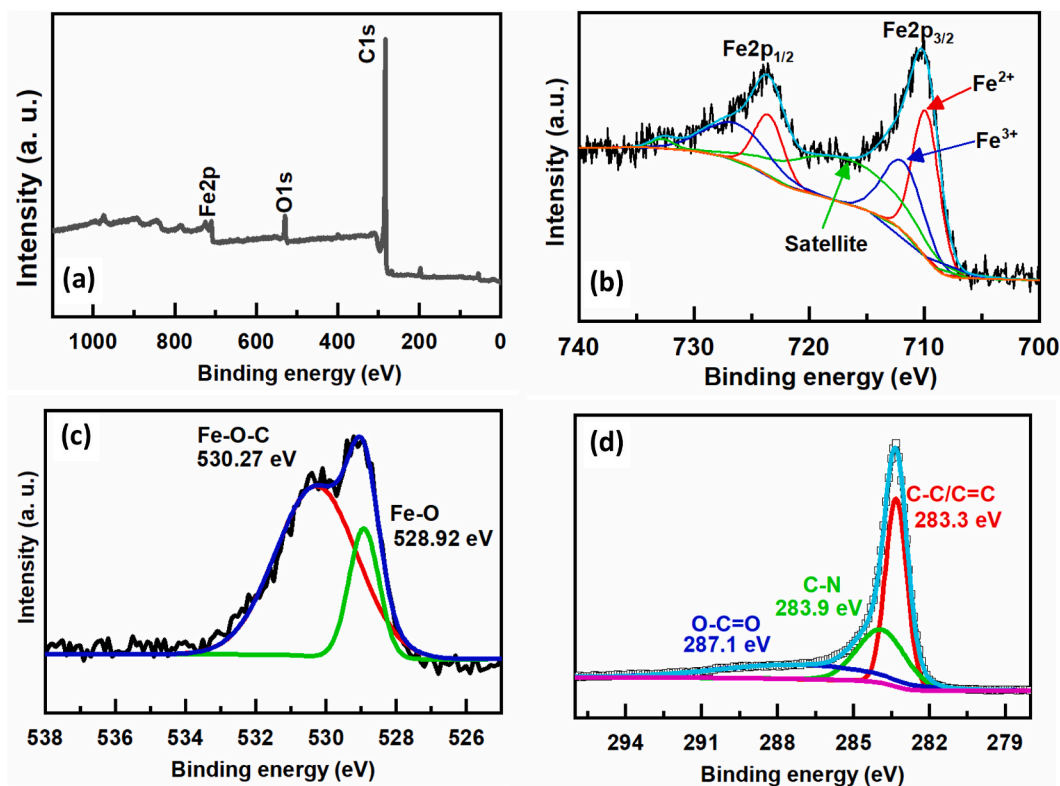

Fig. 2. (a) full XPS spectra of the P1 sample and high-resolution XPS spectra; (b) Fe2p, (c) O1s, and (d) C1s.

Fig. 2d is the C1s spectrum. The binding energy values of 283.30, 283.9, and 287.1 eV are due to the C=C/C–C, C–N, and O–C=O species, respectively [17,40] caused by depositing carbon on the Fe<sub>3</sub>O<sub>4</sub> nanoparticles through burning the organic framework and PVP molecule.

SEM images of the MOF-derived Fe<sub>3</sub>O<sub>4</sub> powders are shown in Fig. 3. The P0 powders are composed of the Fe<sub>3</sub>O<sub>4</sub> nanoparticles (~40 nm) agglomerated on the pores' walls. Burning the organic framework is responsible for the macropores. By adding the PVP, the morphology is transformed from a particular to a rod-like with sheetlike building blocks (Fig. 3c1 and c2). The octahedral morphology of MIL101-(Fe) can be modified by adding PVP. The entanglement of PVP molecules geometrically confine the growth of MIL101-Fe, leading to the elongated octahedral particles as rod-like particles. Furthermore, the PVP additive changes the decomposition rate of MIL101-(Fe) molecules, inducing the sheet-like building blocks [41].

N<sub>2</sub> ad/desorption isotherms of the MOF-derived Fe<sub>3</sub>O<sub>4</sub> powders are presented in Fig. 4a. The fragile agglomeration of Fe<sub>3</sub>O<sub>4</sub> nanoparticles result in the IV type isotherm with H3 hysteresis. The values of BET specific surface area are 150, 206, and 282 m<sup>2</sup>/g for the P0, P1, and P2 samples, respectively. Furthermore, the pore volume slightly increases from 0.50 cm<sup>3</sup>/g for the P0 sample to 0.55 and 0.53 cm<sup>3</sup>/g for the P1 and P2 samples, respectively. The higher specific surface area of the PVP-assisted samples can be attributed to the morphological evolution from particular to rod-like with sheetlike building blocks. The rod-like morphology has the lower packing density, inducing the higher specific surface area. The average size of pores is centered about 10 nm, showing their mesopores' nature. The pyrolysis of the organic materials leads to the gaseous products, inducing the micropores and macropores.

Magnetization curves of the MOF-derived Fe<sub>3</sub>O<sub>4</sub> powders are shown in Fig. 5. The porous powders show S-shaped curve with a hysteresis loop, corresponding to their ferromagnetic behavior. The Fe<sub>3</sub>O<sub>4</sub> phase has a spinel structure in which the magnetic Fe<sup>3+</sup> and Fe<sup>2+</sup> cations are distributed between tetrahedral (A) and octahedral [B] sites [42]. The reversely exchange-coupling of Fe<sup>3+</sup> and Fe<sup>2+</sup> cations via oxygen ions is responsible for the magnetic moments and saturation magnetization of Fe<sub>3</sub>O<sub>4</sub> phase. The unequal magnetic moments of Fe<sup>3+</sup> and Fe<sup>2+</sup> results in the spontaneous magnetization of the Fe<sub>3</sub>O<sub>4</sub> phase as similar to the ferromagnetic materials with magnetic hysteresis loop [43]. The values of saturation magnetization (M<sub>s</sub>) and coercivity (H<sub>c</sub>) are dependent on the PVP contents. With the increase of PVP, the M<sub>s</sub> value first increases from 16 to 47 emu/g and then decreases up to 41 emu/g. The coercivity decreases from 163 to 155 Oe by adding PVP. The magnetic properties are related to the phase purity, cation distribution, particle size and shape [44–46]. With the increase of PVP, the M<sub>s</sub> value first increases from 16 to 47 emu/g and then decreases up to 41 emu/g. The disappearance of nonmagnetic α-Fe<sub>2</sub>O<sub>3</sub> phase is responsible for the increase of M<sub>s</sub> value. However, the decrease of M<sub>s</sub> can be attributed to the spin canting effects [47–49]. The disorderings of magnetic moments at the surface of Fe<sub>3</sub>O<sub>4</sub> nanoparticles lead to the decrease of saturation magnetization.

The permittivity, permeability, and dielectric and magnetic loss factors of the MOF-derived Fe<sub>3</sub>O<sub>4</sub> powders are presented in Fig. 6. The real permittivity (ε') of the P0 sample decreases from 26 to 7.7 in the frequency range of 1–18 GHz. By adding the PVP, the average value of ε' decreases from 16 to 4 (Fig. 6a). Consequently, there is similar trend for imaginary permittivity (ε'') versus frequency (Fig. 6b) in which the ε'' value is sharply decreased in lower frequency region (1–4 GHz) and then it is slowly decreased at higher frequencies. The average ε'' value decreases from 11 to 0.5 by adding the PVP. Furthermore, the ε'' spectra show a broad peak in at the

frequency range of 12–18 GHz. This broad peak is clearly observable in the dielectric loss factor (Fig. 6c). The permittivity spectra can be described based on conduction loss and dipolar polarization phenomena as dielectric loss mechanisms [50]. The higher contribution of conduction loss mechanism leads to the initial substantial decrease of permittivity in the low-frequency region [51]. The flow of electrons in the absorber by incident EMWs is responsible for the conduction loss mechanism. Therefore, the imaginary part ( $\epsilon''$ ) of permittivity as a loss capacity is directly proportional to the electrical conductivity ( $\sigma = \sigma_{ac} + \sigma_{dc}$ ) as follows [52]:

$$\epsilon'' = \frac{\sigma}{2\pi f \epsilon_0} = \frac{\sigma_{ac}}{2\pi f \epsilon_0} + \frac{\sigma_{dc}}{2\pi f \epsilon_0} \quad (1)$$

which  $f$  is frequency of EMWs and  $\epsilon_0$  is vacuum permittivity. The higher contribution of the DC electrical conductivity ( $\sigma_{dc}$ ) than that of the AC conductivity ( $\sigma_{ac}$ ) leads to the initial drop in  $\epsilon''$  values. The term of  $\frac{\sigma_{ac}}{2\pi f \epsilon_0}$  has a constant value because the  $\sigma_{ac}$  is proportional to the frequency ( $f$ ). The broad peak on the  $\epsilon''$  spectra is due to the dipolar polarization mechanism. Among various origins of dipolar polarization, the space charge distribution mechanism is more common for polycrystalline materials. The mobile charges can be accumulated at phase interfaces and grain boundaries, leading to the interfacial dipoles as space charge distribution. According to the Debye model, the electrical energy of EMWs is attenuated by fluctuating the interfacial dipoles [53,54]. The lower permittivity of the P2 powders can be attributed to the porous microstructure of rod-like particles. These pores decrease the electrical conductivity through the reduction of packing density.

Fig. 6d and e shows the dependence of the real ( $\mu'$ ) and imaginary ( $\mu''$ ) parts of permeability spectra versus frequency. All samples show relatively similar values of  $\mu'$  at the whole frequency range (1–18 GHz) in which the  $\mu'$  values decrease from 1.35 to 0.95 due to the deviation of magnetic dipoles' vibrations from alternating applied fields [55,56]. The  $\mu''$  spectra have several broad peaks in the frequency range of 1–16 GHz caused by the various mechanisms of the ferromagnetic resonance. The natural resonance occurs at below 10 GHz, while the exchange resonance become active at above 10 GHz [50]. Moreover, the average value of  $\mu''$  first increases from 0.03 to 0.09 and then decreases to 0.06 with adding the PVP. The permeability values are dependent on the saturation magnetization and magnetic anisotropy of the  $\text{Fe}_3\text{O}_4/\text{C}$  powders which can be adjusted by the PVP contents. Fig. 6f shows the magnetic ( $\tan\delta_m$ ) loss factors versus frequency which is similar to the  $\mu''$  spectra. However, the dielectric loss factor ( $\tan\delta_e$ ) (0.1–0.7) is higher than that of magnetic loss factor ( $\tan\delta_m$ ) (0–0.13), showing the higher contribution of dielectric loss in comparison with the magnetic loss.

Fig. 7 shows the dependence of reflection loss (RL) on frequency and absorber thickness. The reflection loss (RL) can be calculated using the normalized input impedance ( $Z_{in}/Z_0$ ) as follows [57]:

$$RL(\text{dB}) = 20 \log \left| \frac{\frac{Z_{in}}{Z_0} - 1}{\frac{Z_{in}}{Z_0} + 1} \right| \quad (2)$$

$$\frac{Z_{in}}{Z_0} = \sqrt{\frac{\mu_r}{\epsilon_r}} \tanh \left( j \left( \frac{2\pi f t}{c} \right) \sqrt{\mu_r \epsilon_r} \right) \quad (3)$$

which  $Z_0$  is free space impedance,  $f$  is frequency,  $t$  is absorber thickness, also known as matching thickness,  $\epsilon_r$  is relative permittivity, and  $\mu_r$  is relative permeability [58]. An efficient microwave absorber has the deep reflection loss, broad effective absorption bandwidth (EAB) (reflection loss  $< -10$  dB), and small matching thickness. The P0 powders show strong absorption of  $-34$  dB at a matching thickness of 1.6 mm in Ku band. By adding PVP, the minimum RL increases up to  $-42$  dB at a matching frequency of 13 GHz for the matching thickness of 2.1 mm. However, the absorption capacity worsens for the P2 sample with the minimum RL of  $-13$  dB at high-frequency regions (X and Ku bands) and high matching thicknesses (10 mm).

The dependence of EAB on the matching thickness for the P0 and P1 samples is presented in Fig. 8a. The EAB vs. matching thickness has a similar trend in which EAB first sharply increases up to a maximum and then gradually decreases with the increase of matching thicknesses. At the higher matching thicknesses of 2 mm, the P1 sample has a broader EAB than the P0 powders. The P0 absorber has an EAB of 5.9 GHz in the Ku band (12–18 GHz) at a matching thickness of 1.8 mm. However, the P1 sample can effectively absorb 85 % (5.1 GHz) Ku band at a matching thickness of 1.9 mm. The P1 sample shows an EAB of 4.3 (8–12.3) GHz in X band at a matching

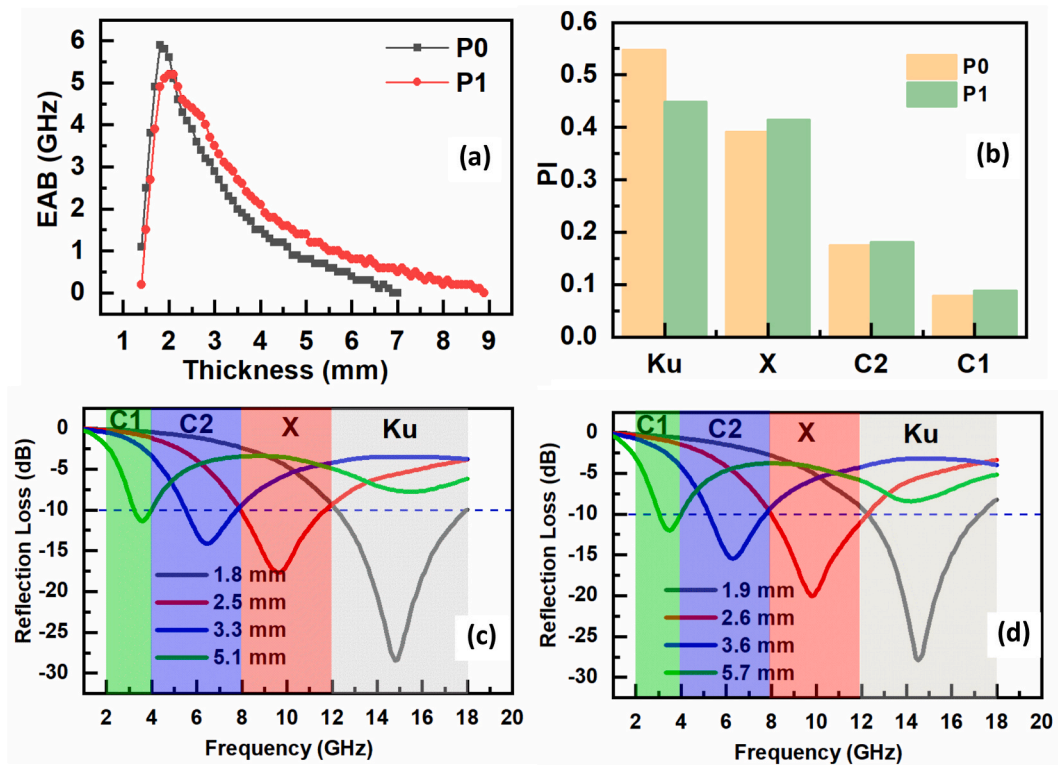

Fig. 7. Dependence of RL values on matching frequency and matching thickness for the MOF-derived  $\text{Fe}_3\text{O}_4$  powders; (a) P0, (b) P1, and (c) P2.

**Fig. 8.** (a) EAB vs. matching thickness, (b) PI for various frequency band, and reflection loss curves at the matching thicknesses which results in the broad EAB for (c) P0 and (d) P1 samples.

thickness of 2.6 mm. A predominance index (PI) for each frequency band is defined as follows [59]:

$$PI = \frac{EAB}{\Delta f_{band} \times t_m} \quad (4)$$

which  $t_m$  is matching thickness and  $\Delta f_{band}$  is the bandwidth of frequency band. The large PI value as a crucial characteristic of the high-performance MAMs is caused by the broad EAB at the small thicknesses. Fig. 8b compares the PI values of the P0 and P1 powders for the different frequency bands. The low-frequency bands have lower PI values. Except of Ku band, the P1 powders have the higher PI values than that of P0 sample. Fig. 8c and d presents the reflection loss curves at the matching thicknesses which show the broad EAB in the frequency band. The P0 and P1 powders effectively absorb the EMWs at small matching thicknesses. However, the minimum reflection loss decreases at the low-frequency bands in which the suitable matching thicknesses are high. The microwave absorption performance of the various  $\text{Fe}_3\text{O}_4$ -based materials is compared in Table 1 by regarding the EAB, matching thickness, and minimum reflection loss. The MOF derived  $\text{Fe}_3\text{O}_4$  powders offer the higher microwave performance due to the adjustment of permittivity and permeability values by adding PVP. Furthermore, the higher microwave performance of MOF-derived  $\text{Fe}_3\text{O}_4$  powders can be attributed to the structural and microstructural features including the high crystallinity, small nanoparticles, and porosity.

The dielectric and magnetic loss mechanisms are responsible for the microwave absorption performance. In the microwave range, the conduction loss and dipolar polarization are active mechanisms of dielectric loss [6]. The dipolar polarization can be modeled by the following Debye equation [61,62]:

**Table 1**  
Microwave absorption performance of the  $\text{Fe}_3\text{O}_4$ -based composites.

$$\varepsilon_r = \varepsilon' - j\varepsilon'' = \varepsilon_{\infty} + \frac{\varepsilon_{r0} - \varepsilon_{\infty}}{1 + j\omega\tau} \quad (5)$$

which  $\tau$  is the relaxation time,  $\omega = 2\pi f$  is the operating angular frequency, and  $\varepsilon_{r0}$  and  $\varepsilon_{\infty}$  are the permittivity values at low and high frequencies, respectively. By removing the frequency ( $\omega = 2\pi f$ ) parameter, the Debye equation is transformed to a circle's equation in  $\varepsilon''$  vs.  $\varepsilon'$  space (Cole-Cole plot) as follows [63,64]:

$$\left(\varepsilon' - \frac{\varepsilon_s + \varepsilon_{\infty}}{2}\right)^2 + (\varepsilon'')^2 = \left(\frac{\varepsilon_s - \varepsilon_{\infty}}{2}\right)^2 \quad (6)$$

Fig. 9a shows the Cole-Cole plots. There are semicircles and inclined linear regions which are respectively due to the dipolar polarization and the conduction loss [65]. The dipolar polarization is categorized on the base of dipoles' origin; the orientational, spontaneous, space charge, and interfacial polarization. In the polycrystalline and composite powders, the interfacial relaxation is mainly active due to a plenty of phase interfaces [66]. A wide region of inclined linear in the Cole-Cole plot indicates the higher contribution of conduction loss in the P0 and P1 powders. However, the lower contribution of conduction loss in the P2 powders leads to the shorter linear part. The porous rod-like morphology of P2 sample is responsible for the lower packing density and then the lower conductivity. In other words, the microwave absorption performance is weakened by changing the morphology from particular to rod-like because of the weakening of the conduction loss, leading to the lower permittivity.

The ferromagnetic resonance and eddy-current effect are two main mechanisms for magnetic loss in the microwave range [67]. Several broad peaks in  $\mu''$  spectra (Fig. 6e) are due to the ferromagnetic resonance phenomena in the  $\text{Fe}_3\text{O}_4$  nanoparticles. The ferromagnetic resonance frequency of bulk  $\text{Fe}_3\text{O}_4$  is in the MHz range due to the low anisotropy field of its spinel structure [68]. However, the  $\text{Fe}_3\text{O}_4$  nanoparticles have the higher anisotropy field due to the surface anisotropy [69]. The  $\text{Fe}_3\text{O}_4$  nanoparticles have the higher surface disorders due to the higher atoms at their surface. Therefore, the  $\text{Fe}_3\text{O}_4$  nanoparticles with higher magnetic anisotropy show the resonance frequency in the GHz region [68]. The contribution of eddy current loss can be determined by considering the dependence of  $\mu'' \mu'^{-2} f^{-1} = 2\pi\mu_0 d^2 \sigma = C_0$  values on frequency ( $f$ ) [7], as shown in Fig. 9b. In the frequency range that the  $C_0$  values remain constant, the magnetic loss mechanism is eddy-current effect. The P0, P1, and P2 samples have similar trends of  $C_0$  values. The  $C_0$  values first decrease and then become constant at above 14 GHz, indicating the predominance of the eddy-current effect in the high-frequency region. The attenuation of EMWs per unit distance inside the absorber is determined by the attenuation ( $\alpha$ ) coefficient which is related to the permittivity and permeability parameters as follows [70]:

$$\alpha = \frac{\sqrt{2\pi f}}{c} \sqrt{(\mu''\varepsilon'' - \mu'\varepsilon') + \sqrt{(\mu''\varepsilon'' - \mu'\varepsilon')^2 + (\mu'\varepsilon'' + \mu''\varepsilon')^2}} \quad (7)$$

Fig. 9c shows the  $\alpha$  coefficient vs. frequency. The P0 powders have the  $\alpha$  values in the range of 38–225. However, by decreasing the permittivity values, the maximum of  $\alpha$  values decreases to 180 and 33 for the P1 and P2, respectively.

For a high-performance MAM, the values of permittivity and permeability provide the impedance matching between the free space ( $Z_0$ ) and absorber ( $Z_{in}$ ), i.e.,  $Z_0 = Z_{in}$  [71,72]. By matching the impedances, the EMWs are not reflected from the surface of absorber, and then the incident EMWs easily enter into the absorbers. The frequency and thickness for matching the impedances can be evaluated by regarding two criteria; (1) the further closeness of  $|Z| = |Z_{in}/Z_0|$  to  $\sim 1$ , the better impedance matching [73] and (2) the smaller delta-function,  $|\Delta| = |\sinh^2(Kfd) - M|$ , the better the impedance matching. The real values of  $K$  and  $M$  are determined as follows [74]:

$$K = \frac{4\pi\sqrt{\varepsilon'\mu'}}{c} \frac{\sin\left(\frac{\delta_e + \delta_m}{2}\right)}{\cos\delta_e \cos\delta_m} \quad (8)$$

$$M = \frac{4\mu' \cos\delta_e \times \varepsilon' \cos\delta_m}{(\mu' \cos\delta_e - \varepsilon' \cos\delta_m)^2 + \left(\tan\left(\frac{\delta_m - \delta_e}{2}\right)\right)^2 (\mu' \cos\delta_e + \varepsilon' \cos\delta_m)^2} \quad (9)$$

Fig. 10 shows the 2D contours of  $|Z|$  and  $|\Delta|$  values versus thickness and frequency. The matching impedance region ( $0.5 < |Z| < 1.5$  and  $|\Delta| < 0.4$ ) is narrow for the P0 powders (Fig. 10a and b). By adding PVP, the absorber and free-space impedances are matched at the broader ranges of frequency and thickness (orange region) due to the decrease of permittivity (Fig. 10c and d). However, the P2 powders with very low permittivity satisfy the impedance matching condition ( $|Z| \sim 1$ ) in a linear region (Fig. 10e). Furthermore, there is no region of frequency and thickness for delta-function condition ( $|\Delta| < 0.4$ ) by the P2 powders, indicating the reflection of incident EMWs. Therefore, the very weak microwave absorption performance of the P2 powders is caused by the mismatching of impedance.

In summary, the high magnetic properties of the  $\text{Fe}_3\text{O}_4$  phase are helpful for the magnetic loss through the ferromagnetic resonance and eddy-current mechanisms [75,76]. The high electrical conductivity of  $\text{Fe}_3\text{O}_4$  is also benefitted for the conduction loss. However, the change of morphology from particular to rod-like by adding high amounts of PVP decreases the permittivity through weakening the conductivity. Furthermore, the contribution of interfacial relaxation in dielectric loss is lower than the contribution of conduction loss, as shown by Cole-Cole plot. Therefore, the rod-like morphology shows the weak absorption performance due to the very low permittivity, leading to the impedance mismatching. However, the proper amounts of PVP additive increase the permeability, leading to the higher microwave absorption performance through matching the impedances. Furthermore, the deposited carbon on the  $\text{Fe}_3\text{O}_4$  nanoparticles can increase the electrical conductivity and dielectric loss. However, there is a contrasting trend of downsizing  $\text{Fe}_3\text{O}_4$

Fig. 9. (a) Cole-Cole plots, (b) C0 versus frequency, and (c) attenuation coefficient vs. frequency.

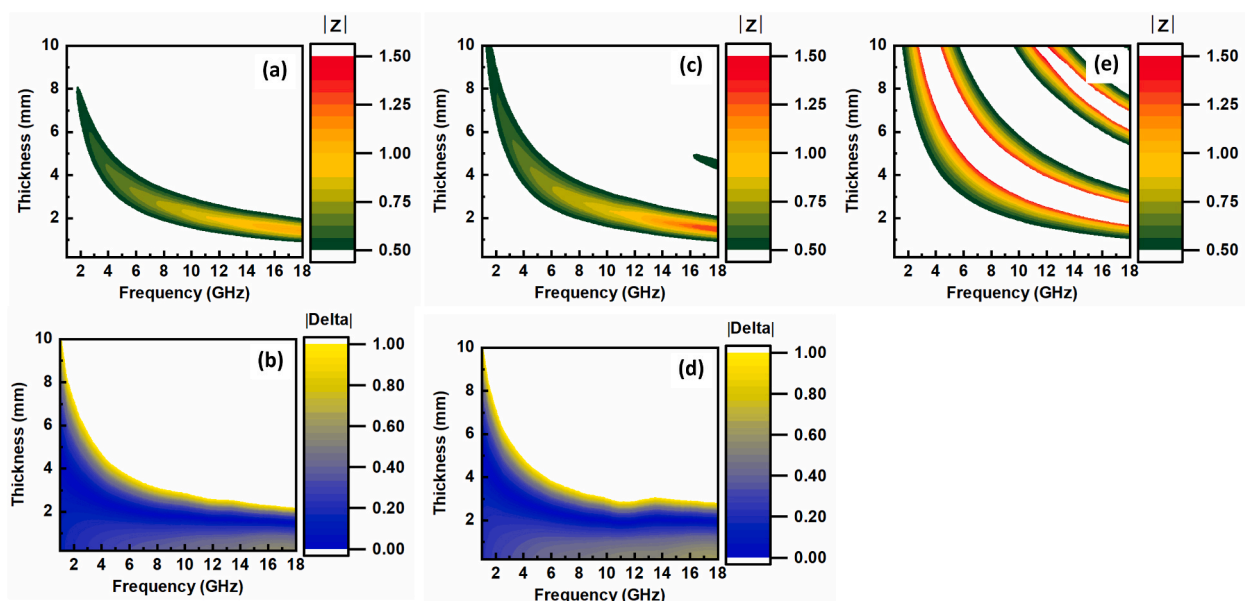

Fig. 10. Contour of  $|Z|$  and  $|\Delta|$  values versus thickness and frequency for (a and b) P0, (c and d) P1, and (e) P2.

nanoparticles. At the higher PVP additives, the higher deposited carbon, but the average size of  $\text{Fe}_3\text{O}_4$  nanoparticles decreased. The higher deposited carbon led to higher electrical conductivity, while the smaller particle size decreased the conductivity. In other words, despite the higher residual carbon at the P2 sample, its conductivity was lower due to its very small particle size.

#### 4. Conclusion

The MOF approach was modified by adding PVP for preparing the porous  $\text{Fe}_3\text{O}_4/\text{C}$  powders. The application of PVP led to the morphology transformation from particular to rod-like which increased the specific surface area from 150 to 282  $\text{m}^2/\text{g}$ . By adding the PVP, the saturation magnetization increased from 16 to 47 emu/g due to the disappearance of antiferromagnetic  $\alpha\text{-Fe}_2\text{O}_3$  phase and improvement of the crystallinity. Despite the decrease of permittivity values, the permeability first increased and then decreased with PVP content. By approaching the permittivity and permeability, the microwave absorption performance of the  $\text{Fe}_3\text{O}_4/\text{C}$  powders improved at a proper amount of PVP additive.
